Asbestos manufacturing, more so than asbestos mining, is associated with pulmonary fibrosis and lung cancer and also the development of malignant pleural mesothelioma. Asbestos workers who also smoke have a synergistic or multiplicative risk of lung cancer over those who do not smoke. Lung cancer in asbestos-exposed persons usually manifests in a setting of pulmonary asbestosis (interstitial fibrosis). It is believed by some investigators that the fibroinflammatory scarring process of pulmonary asbestosis creates a microenvironment in which cancers develop. On the other hand, other researchers propose that the fibrogenic sequence of interstitial fibrosis due to high asbestos fiber burden may not be the same as the carcinogenic pathway of asbestos-induced malignancies. Both pulmonary fibrosis and asbestos-related bronchogenic carcinomas are dose-dependent on the lung fiber burden. Although pulmonary asbestosis tends to predominate in the lower lobes, the asbestos-induced cancers are found in all lobes of the lung. In the case of pleural diffuse malignant mesothelioma, the tumor may be attributable to asbestos exposure even in the absence of pulmonary fibrosis or smoking.

SURGICAL PATHOLOGY AND CYTOPATHOLOGY

The malignant epithelial tumors of the lung consist of the most common bronchogenic carcinomas: adenocarcinoma, squamous cell carcinoma, small cell carcinoma, and large cell carcinoma, and their subgroups. Less common malignant epithelial tumors include the sarcomatoid carcinomas, neuroendocrine-carcinoid tumors, and salivary gland tumors. Most tumors of the lung are advanced at presentation and tend to be higher-stage cancers. Cancers of the central airways are commonly diagnosed and may occur as an endobronchial mass or as a parenchymal mass with endobronchial extension or extrinsic bronchial compression and a possible resultant obstructive pneumonia. Clinically, affected patients present with cough, hemoptysis, and/or shortness of breath. The central tumors may be approached by interventional bronchoscopy for diagnosis and management. Those tumors that manifest as peripheral scars or solitary pulmonary nodules may be histopathologically assessed by needle core or aspiration biopsy.

Cytologic evaluation of sputum, bronchial washings or brushings, and fine needle aspiration (FNA) biopsy specimens (transbronchial, transesophageal, or percutaneous) has long been utilized in the diagnostic workup of lung masses and as a staging procedure by sampling hilar or mediastinal nodes. The diagnostic accuracy is highly dependent on the sampling method. Cytologic approaches in the right clinical setting can provide valuable information without the need for an invasive procedure such as mediastinoscopy. More recently, it has been shown that the addition of ultrasound guidance to the bronchoscopy or endoscopy procedure improves diagnostic accuracy, with sensitivity of more than 85% and specificity of 100%.

Traditionally, the role of cytologic analysis was to first establish the diagnosis of malignancy and then to further stratify the carcinoma into two main categories of small cell carcinoma and non–small cell carcinoma, for appropriate management. With the advent of targeted therapy, however, this approach no longer provides the necessary information, because major changes have evolved in the treatment of squamous cell carcinoma and adenocarcinoma that may involve approaches dependent on the presence or absence of genetic mutations. Several studies have addressed the feasibility and accuracy of cytologic studies in this respect, especially when immunohistochemical methods are used in conjunction with cytomorphologic examination. Furthermore, it has been shown that molecular studies for *EGFR/KRAS* mutation analysis can be successfully carried out on cytologic preparations.

Adenocarcinoma

Adenocarcinomas are tumors that produce malignant-appearing glands with tubular, acinar, or papillary differentiation and whose cells may demonstrate mucin production and secretion (Box 65-1). On gross examination, the tumors may manifest peripherally with pleural retraction (puckering), as central or endobronchial masses, as diffuse pleural involvement resembling a malignant mesothelioma, arising or associated with a scar, or as a diffuse parenchymal pneumonic-like tumor. The histologic pattern and organization may show a well-differentiated acinar pattern with intracytoplasmic vacuoles or more poorly differentiated features with solid malignant growth

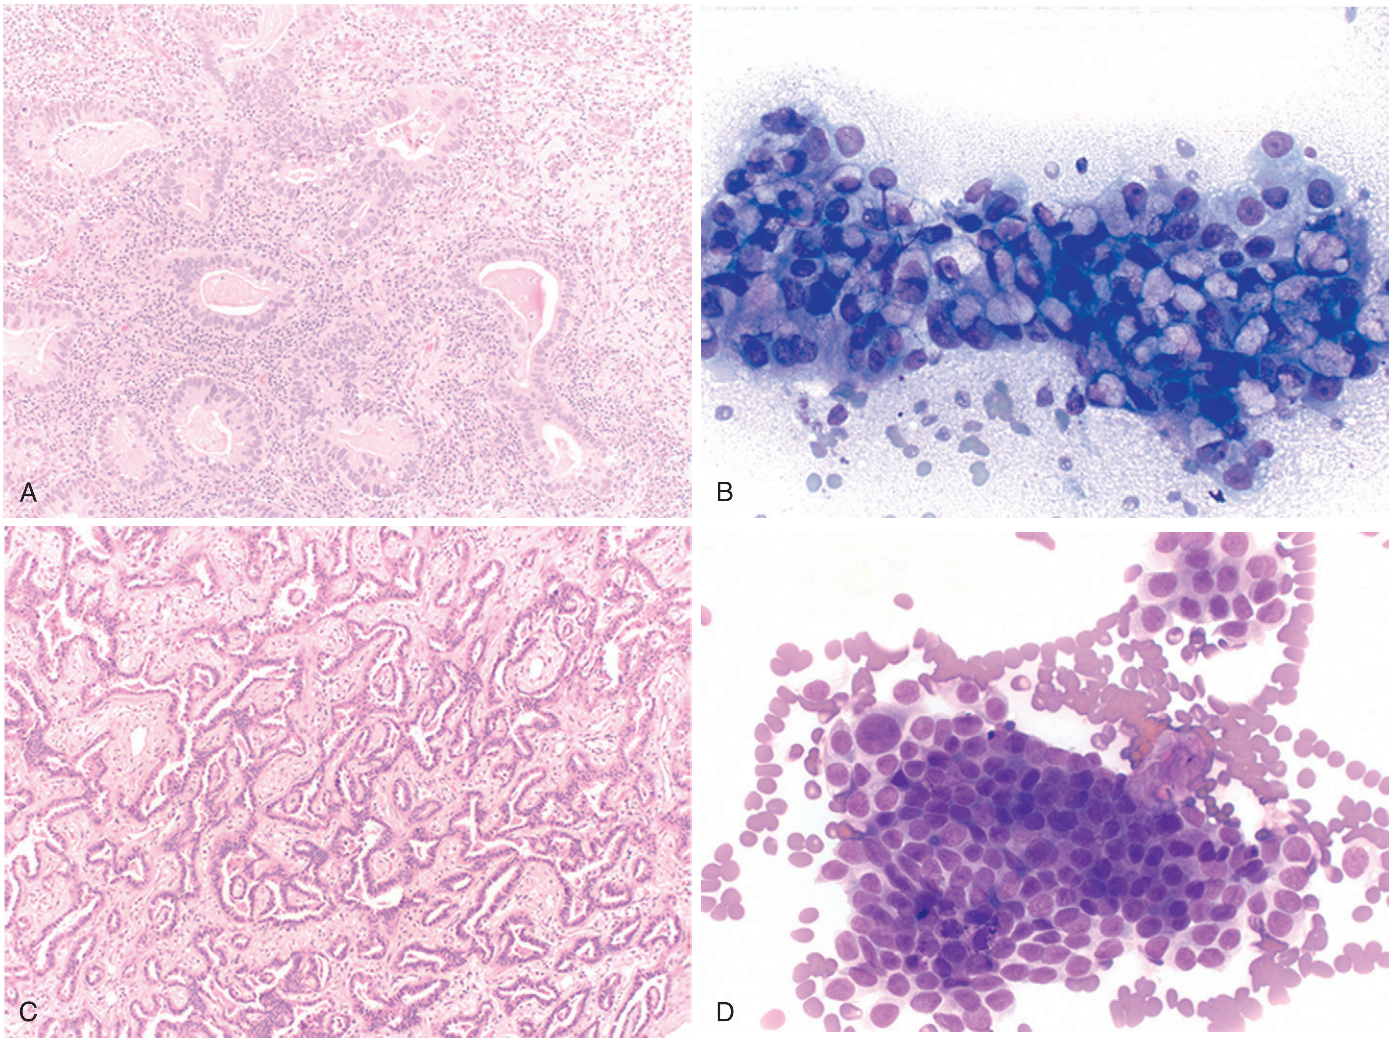

Figure 65-2 Adenocarcinoma, acinar type. **A,** Adenocarcinoma with acinar growth pattern. (Hematoxylin-eosin stain [H&E], 10×.) **B,** Cytologic preparation showing intracytoplasmic vacuoles. (Diff-Quik stain, 40×.) **C,** Adenocarcinoma with tubuloacinar growth pattern. (H&E, 10×.) **D,** Cytologic preparation showing sheetlike growth and intracytoplasmic vacuoles. (Diff-Quik stain, 40×.)

pattern and minimal mucin expression, as demonstrated by histochemical and/or immunohistochemical staining assays. In some cases, the intracytoplasmic vacuole distends the cytoplasm and compressively deforms the nucleus to the cell margin, forming a "signet-ring" cell. The tumors may arise at various levels of the airway with malignant changes in respiratory, bronchiolar, and alveolar epithelium. Malignant transformation of these various epithelia may be associated with protean histologic and cytologic characteristics and growth patterns of invasion.

The nature of tumor growth and progression depends on whether the cell of origin is a bronchial gland, ciliated columnar cell, goblet cell, nonciliated bronchiolar cell, or type II pneumocyte. The histologic growth pattern may show a mixture of various types including acinar, papillary, solid, and lepidic (growth along alveolar interstitium), and the cytologic features may include mucinous and nonmucinous differentiation (Figures 65-2 and 65-3). The grading of adenocarcinomas is based on the histopathologic assessment of the extent of glandular differentiation and architectural pattern, cytologic expression and pleomorphism, nuclear characteristics and stratification, and mitotic activity and tumor necrosis. Most adenocarcinomas tend to be of mixed pattern, are intermediate in differentiation or moderately differentiated, and show a predominant acinar-type glandular arrangement. As expected, predominantly solid adenocarcinomas tend to demonstrate high-grade, poorly differentiated cytologic features with prominent mitotic activity and tumor necrosis. Adenocarcinomas may have clear cell features resulting from the accumulation

Box 65-1 Classification of Adenocarcinoma in Resected Specimens

Preinvasive Lesions
Atypical adenomatous hyperplasia (AAH)
Adenocarcinoma in situ (AIS)
Nonmucinous, mucinous, or mixed types

Minimally Invasive Adenocarcinoma (MIA)
Nonmucinous, mucinous, or mixed types

Invasive Adenocarcinomas
Predominant types: lepidic, acinar, papillary, micropapillary, solid
Adenocarcinoma, variants: invasive mucinous, colloid, fetal, enteric

Modified from Travis WD, Brambilla E, Noguchi M, et al: International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society international multidisciplinary classification of lung adenocarcinoma, *J Thorac Oncol* 6:244–285, 2011.

of intracellular glycogen or mucins, and such tumors must be differentiated from metastatic clear cell renal carcinomas; the presence of intracytoplasmic lipid and glycogen is diagnostic of renal tumors of the clear cell type.

Histopathologic characteristics that correlate with a relatively poor prognosis in adenocarcinomas of the lung include a predominant solid pattern and high-grade cytologic features with mitotic figures and tumor necrosis, a micropapillary relative to a papillary histologic pattern, extension to and involvement of the visceral pleura, extensive lymphovascular tumor embolic spread, involvement of bronchial and hilar lymph nodes, and tumor-associated secondary obstructive lobar pneumonia. In addition, resection specimens that show intralobar satellite (metastatic) nodules and involvement of the surgical resection margins are associated with disease recurrence.

The histologic subtypes of adenocarcinoma appear to correlate with a history of cigarette smoking. Relative to nonsmokers, smokers more often have adenocarcinoma of the solid histologic type, and the extent of the solid component within the adenocarcinoma shows a dose-response relationship with pack-years of smoking. The solid subtype of adenocarcinoma also demonstrates a higher frequency of lymphovascular invasion and pleural involvement, and these histopathologic features are predictive for recurrence in stage I adenocarcinoma.

Historically, the most common cases of pulmonary adenocarcinoma were of the mixed type, with several histologic subtypes, and often the tumor had a so-called bronchioloalveolar carcinoma (BAC) growth margin. As originally defined, BAC is characterized by a lepidic growth pattern with atypical tumor cells (nonmucinous serous cells or mucinous cells) proliferating along the interstitial framework and not demonstrating stromal invasion or lymphovascular invasion. Tumors that manifest a BAC pattern often exhibit "ground glass" features on radiographs, and mixed-type invasive adenocarcinomas have central solid density with parenchymal distortion.

As a result of improper utilization and ambiguity of these pathologic terms, a group of international societies proposed a new classification that incorporated the histopathologic pattern, the radiographic features, and the clinical presentation and outcome. On the basis of the accumulated clinical experience with cases in which tumors 3 cm or less in diameter, with a pure lepidic growth pattern, were completely excised, followed by excellent survival, the term *adenocarcinoma in situ* (AIS) was adopted. These preinvasive lesions were judged to be extensions of a precursor lesion, termed *atypical adenomatous hyperplasia* (AAH), which also showed a lepidic growth pattern but were smaller in size (up to 5 mm in diameter). Those tumors that demonstrated an overall AIS pattern but also contained central minimal stromal invasion (less or equal to 5 mm) were

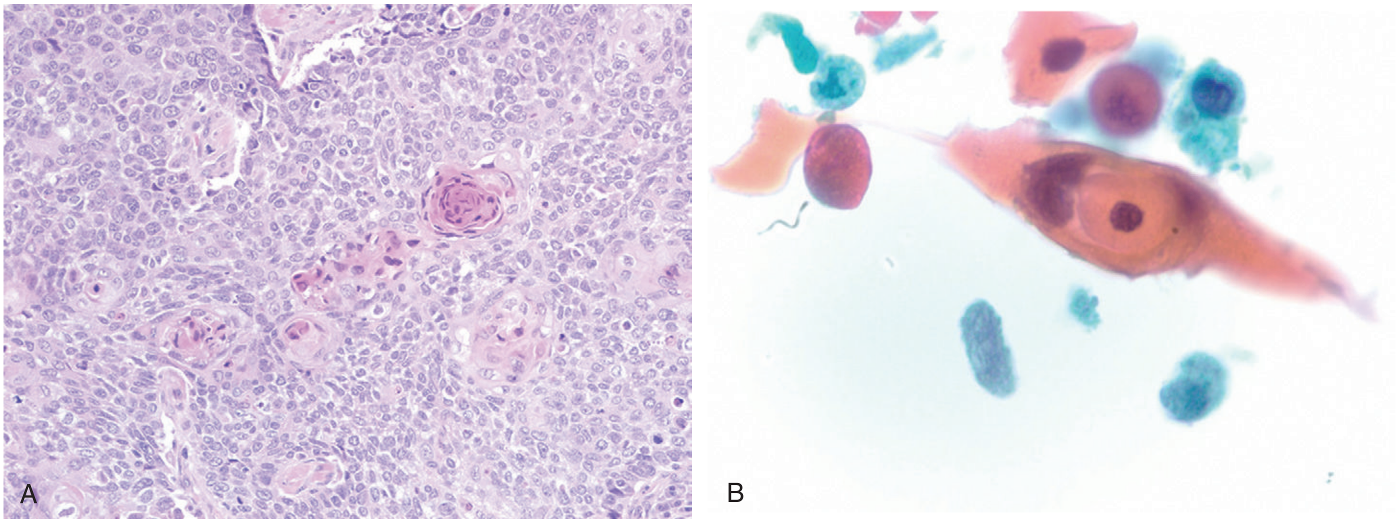

Figure 65-4 Squamous cell carcinoma. **A,** In this preparation, note the keratin pearl. (Hematoxylin-eosin stain, 20×.) **B,** Cytologic preparation showing cytoplasmic keratinization. (Papanicolaou smear, 100×.)

designated *minimally invasive adenocarcinoma* (MIA). These latter cancers usually are nonmucinous and are associated with an excellent clinical outcome. In order to render a diagnosis of AIS or MIA, the entire lesion must be excised and processed for microscopic evaluation. These tumor types are excluded when histologic features of lymphovascular invasion, pleural involvement, and tumor necrosis are identified. It is recommended that the designation BAC be abandoned and that in its place, the proper histologic classification be applied, which may be AIS, MIA, adenocarcinoma with a predominant or mixed lepidic pattern, or mucinous adenocarcinoma. Tumors that were historically diagnosed as "nonmucinous BAC" may now occur as AIS, MIA, or lepidic-dominant adenocarcinomas. Many of these cases tend to be found in women, with immunohistochemical profiles of CK7 and thyroid transcription factor-1 (TTF-1) immunoreactivity and frequent epidermal growth factor receptor (EGFR) mutational status. By contrast, the historical designation of "mucinous BAC" is recommended to be changed to *invasive mucinous adenocarcinoma*, with immunohistochemical profiles of CK20 immunoreactivity and nonreactivity for TTF-1. These tumors frequently are associated with *KRAS* mutation and no *EGFR* mutation.

Invasive adenocarcinomas, representing a considerable majority (greater than 75% of cases), are those that exhibit significant stromal invasion and possible lymphovascular invasion and infiltration of the visceral pleura. These cancers need to be measured, because the size of the invasive component governs the tumor-node-metastasis (TNM) staging and the potential for tumor dissemination. The classification also recommends that the predominant pattern of the adenocarcinoma be designated and that the term "mixed pattern" be abandoned. The assessment of the components of the adenocarcinoma not only is important for the proper classification but also is useful for the correct identification of multiple pulmonary nodules as either multiple primary tumors or T3 or T4 tumors. Obviously, tumors that differ in histologic pattern and those that have an in situ component represent multiple primary tumors. It also is possible to differentiate whether the separate nodules are multiple T1 tumors by determining the relative distribution of the adenocarcinoma subtypes. For example, two nodules of adenocarcinoma may be regarded as separate T1 tumors if one is predominantly of the acinar subtype while the other nodule lacks the acinar pattern and is composed of predominant solid variant.

The consensus classification also addressed the recommended approach with small biopsy specimens (a common problem with fiberoptic biopsy samples) and cytologic preparations. The pathologist must make every attempt to avoid the diagnosis of "lung cancer not otherwise specified," because the identification of a characteristic histologic pattern is important for tumor management. In a majority of cases, the distinction between adenocarcinoma and squamous cell carcinomas may be made using routine hematoxylin-eosin–stained (H&E) sections. In those cases of poorly differentiated carcinomas, mucin histochemical methods and a limited panel of immunohistochemical stains may achieve a more definitive result. Adenocarcinomas will show luminal or intracytoplasmic mucin positivity and TTF-1 immunoreactivity. Squamous cell carcinomas will lack mucin staining and will demonstrate reactivity for p63 or CK5/6 but not TTF-1.

Squamous Cell Carcinoma

Squamous cell carcinoma is a malignant tumor arising from bronchial epithelium with a strong etiologic association with cigarette smoking, in contrast with adenocarcinoma. It most commonly is central in location and arises from the main, lobar, or segmental bronchi. Squamous cell carcinomas usually appear as white or gray masses with a variable degree of fibrosis, frequently associated with central necrosis and cavitations. Histologic hallmarks of squamous origin, namely keratinization and intercellular bridges, are seen in relation to the degree of the differentiation; although readily appreciated in well-differentiated tumors, they may be only focally present or even absent in poorly differentiated ones (Figure 65-4). In selected cases, when squamous nature cannot be ascertained by routine light microscopy, immunohistochemistry studies are invaluable. Squamous cell carcinomas usually are immunoreactive for high-molecular-weight keratin, CK5/6, and p63 and generally are nonreactive for TTF-1, CK7, and neuroendocrine markers (CD56, synaptophysin, chromogranin). Although not widely used, electron microscopy also can highlight features of squamous differentiation, such as prominent desmosomes and cytoplasmic aggregates of intermediate keratin filaments.

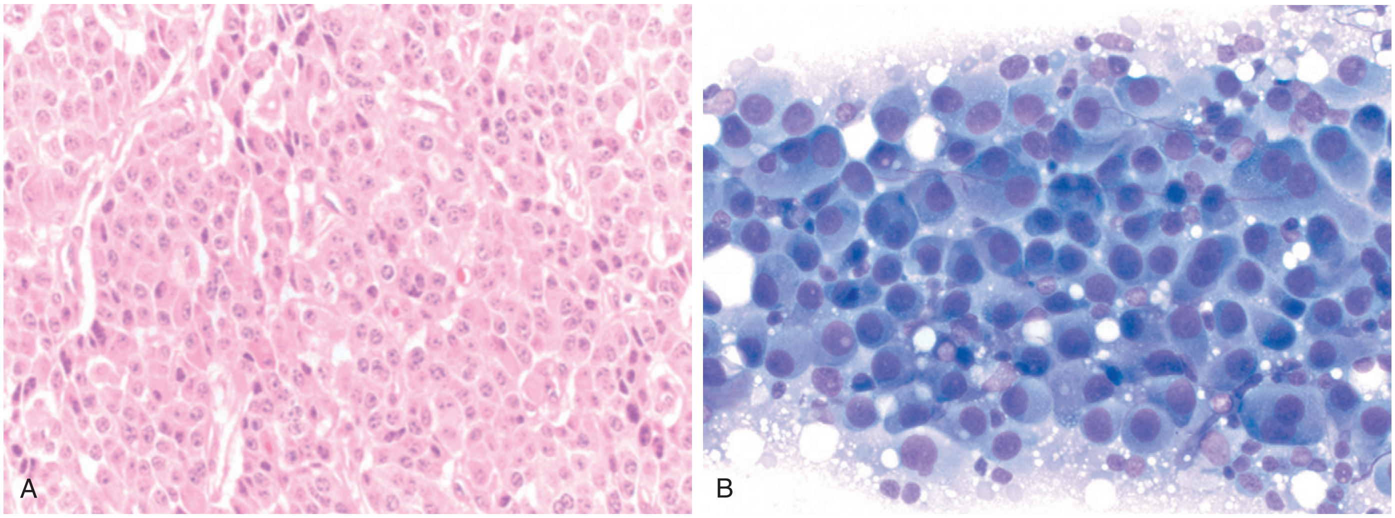

Figure 65-5 Carcinoid tumor. **A,** Note the nesting arrangement of cells. (Hematoxylin-eosin stain, 40×.) **B,** Cytologic preparation showing a uniform cellular pattern. (Diff-Quik stain, 40×.)

Recognizing histologic variants of squamous cell carcinoma, including papillary, clear cell, small cell, and basaloid types, is useful mainly in excluding the various differential diagnostic considerations. Their behavior is primarily a reflection of the degree of differentiation, with basaloid and small cell variants portending a worse outcome.

Pattern of spread is somewhat different depending on the anatomic location. Central tumors either grow along the epithelium, with or without invasion into subepithelial tissue, or expand as an endobronchial polypoid growth. In advanced cases, these tumors may directly involve hilar mediastinal tissue, including lymph nodes. Peripheral tumors, on the other hand, form a solid nodule and may directly break through the pleura into the chest wall or diaphragm.

Staging is governed by the TNM system. Regardless of the location, squamous cell carcinomas are more likely to be locally aggressive and invade adjacent structures. Distant metastasis, albeit far less common than with other subtypes of lung cancer, has a predilection for brain, liver, adrenals, lower gastrointestinal tract, and distant lymph nodes. In general, squamous cell carcinomas are associated with better prognosis and survival rate, as compared with stage-matched adenocarcinomas.

Small Cell Carcinoma and Neuroendocrine (Carcinoid) Tumors

Neuroendocrine tumors, those that contain dense core neurosecretory granules composed of serotonin, histamine, and other bioactive amines, include small cell and large cell neuroendocrine carcinomas and typical and atypical carcinoid tumors. As a group, these tumors represent about one fifth of primary lung neoplasms, with small cell carcinoma being the most common in this category. These tumor types share a histologic pattern of uniform to pleomorphic cells in an organoid arrangement of tumor nests and trabecula (Figure 65-5). Carcinoid tumors may be considered as well-differentiated neuroendocrine carcinomas with little to no mitotic activity (less than 2 mitotic figures per 2-mm^2 microscopic field) or tumor necrosis. Carcinoid tumors may occur in nonsmokers, in whom they manifest as a vascular rich endobronchial mass, although some carcinoid tumors may have a peripheral localization and have spindle cellular features. The tumors are low-grade malignancies with approximately 15% nodal metastases at diagnosis; nevertheless, affected patients have a greater than 90% 5-year survival. The atypical carcinoid tumors are neuroendocrine carcinomas of intermediate grade that have an organoid arrangement with more irregular and atypical cytologic pattern, identifiable tumor necrosis, and countable mitotic activity (2 to 10 mitoses per 2-mm^2 microscopic field). In contrast with typical carcinoid tumors, atypical carcinoid may have nearly 50% lymph node metastases on presentation and a lower 5-year survival rate.

The high-grade poorly differentiated neuroendocrine tumors consist of the small cell (neuroendocrine) carcinoma and the large cell neuroendocrine carcinoma. The latter two have, respectively, smaller and larger cells with considerable cytologic atypia, prominent mitotic activity (more than 10 mitotic figures per 2-mm^2 microscopic field), and abundant tumor necrosis. All of the neuroendocrine tumors will be immunohistochemically reactive with broad-spectrum cytokeratins, CD56, and, specifically, immunoreactive for neuroendocrine markers, such as chromogranin and synaptophysin. The high-grade neuroendocrine carcinomas are immunoreactive for TTF-1, more so than are the intermediate-grade and well-differentiated types.

Close attention to the morphologic details in conjunction with ancillary studies is important to differentiate small cell carcinoma not only from non–small cell carcinoma but also from other neuroendocrine tumors of lung, because they differ substantially in their demographics, clinical presentation, and behavior. Small cell carcinoma of lung generally is a disease of elderly men (mean age, 65 years) who are almost always current or former heavy smokers. These demographic findings are in sharp contrast with those in patients with typical carcinoid, who present at a younger age (mean, 45 to 50 years), with no difference in regard to gender or smoking history. The disparity also extends to associated prognosis and clinical behavior. Whereas typical carcinoid tumors are known for their indolent behavior and excellent survival rates, small cell carcinomas, at the other end of the spectrum, are fatal, with many patients presenting with distant metastasis at the time of diagnosis. Small cell carcinomas typically are central in location and frequently appear radiographically as hilar or perihilar masses with mediastinal lymphadenopathy and lobar collapse. Extensive necrosis is almost always present.

The key histopathologic features in the diagnosis of small cell carcinoma are nuclear morphologic features, such as finely

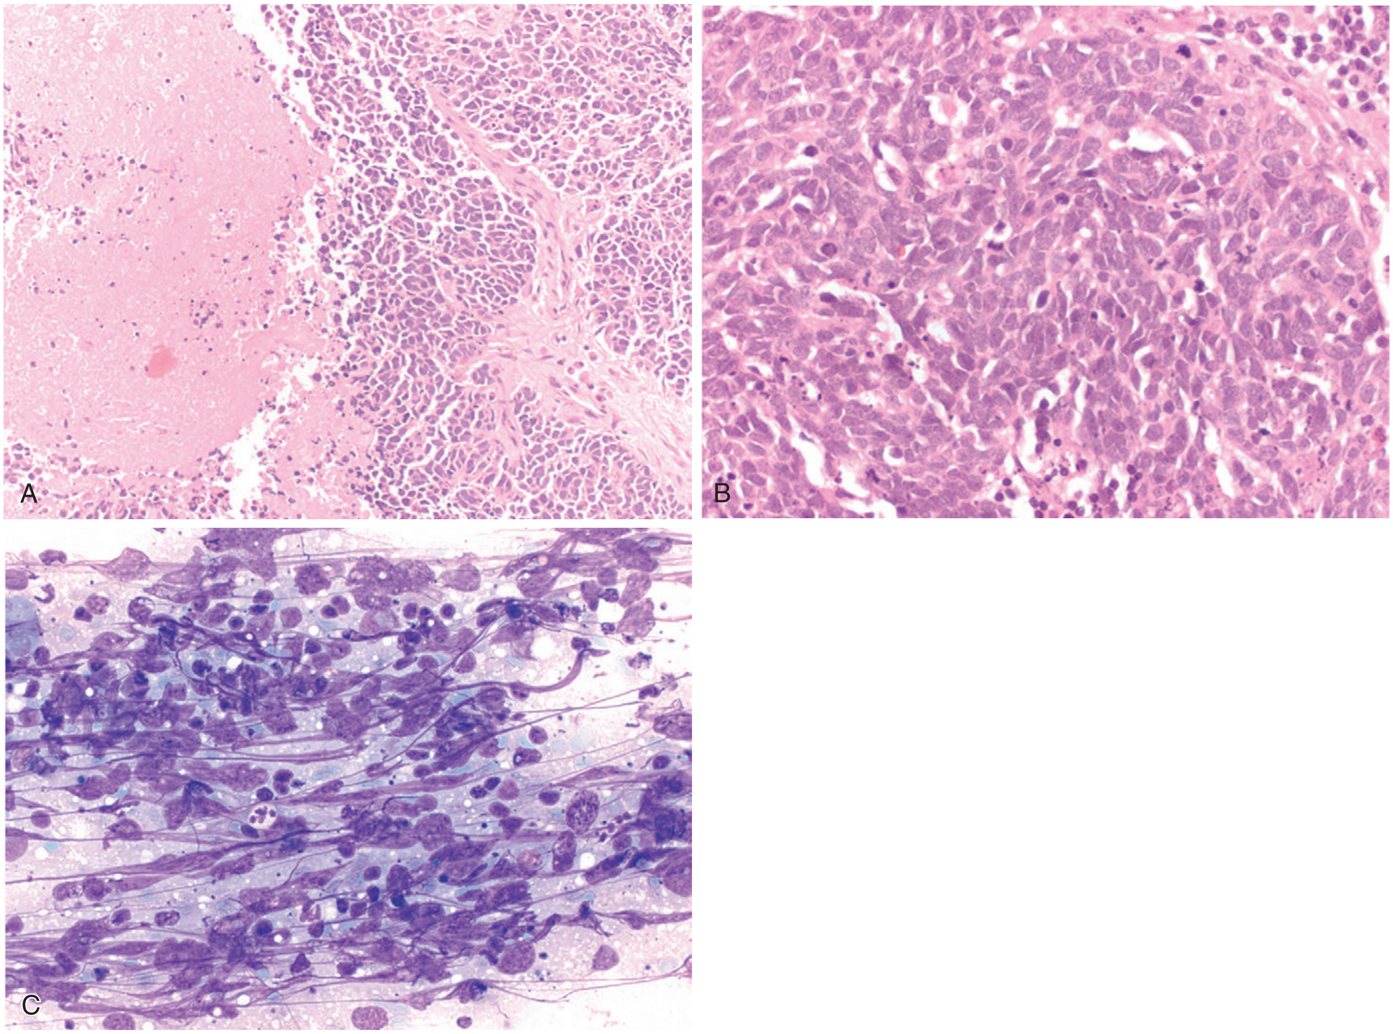

Figure 65-6 Small cell carcinoma. **A,** In this preparation, note the partial nesting pattern and tumor necrosis. (Hematoxylin-eosin stain [H&E], 20×.) **B,** Nuclear molding and mitotic activity are evident in this preparation. (H&E, 40×.) **C,** Cytologic preparation showing inconspicuous cytoplasm and nuclear fragmentation. (Diff-Quik stain, 20×.)

granular chromatin, absence of prominent nucleoli, fragility, molding, and extensive crush artifact, as well as indistinct cytoplasmic borders and high mitotic figure count (more than 10 per 10 high-power fields) (Figure 65-6). Large zones of geographic necrosis also are common. Classically, a great deal of emphasis was placed on the small cell size or nuclear size, as suggested by the nomenclature. The usefulness of this criterion is questionable, however, in view of the wide variability in size, with frequent overlap with large cell neuroendocrine carcinomas. Large cell neuroendocrine carcinomas show a low-power neuroendocrine architecture, as seen in carcinoid tumors; however, the cell morphology closely resembles that of non–small cell carcinomas, with vesicular chromatin, prominent nucleoli, and abundant cytoplasm—features completely different from those of small cell carcinoma (Figure 65-7). Additionally, these tumors are highly mitotic (more than 10 mitotic figures per 10 high-power fields) and often show extensive necrosis, similar to that in small cell carcinomas, and in keeping with their high-grade nature.

Positive immunoreactivity with at least one neuroendocrine marker (synaptophysin, chromogranin) is required for the diagnosis of small cell carcinoma. By contrast, the main role of immunohistochemistry studies in small cell carcinoma is to exclude a wide range of other high-grade round blue cell tumors in the differential diagnosis. Cytokeratin immunoreactivity, especially the characteristic dotlike positivity, aids in excluding a lymphoid process, reactive or neoplastic, in instances of considerable morphologic overlap, particularly in small and poorly preserved samples. However, strong membranous staining with cytokeratins and diffuse staining with 34βE12 are characteristic of non–small cell carcinomas and generally are not seen in small cell carcinoma. The neuroendocrine markers synaptophysin and chromogranin, although strongly expressed in carcinoid, may be very focal in location or entirely absent in small cell carcinoma, and in such cases, CD56 is a more sensitive indicator of neuroendocrine differentiation. TTF-1, a very useful marker in establishing lung origin in adenocarcinoma, is seen in an overwhelming majority of small cell lung carcinomas, but it also may be expressed by extrapulmonary small cell carcinomas such as bladder and prostate cancers and therefore cannot be used to establish the site of origin. Although Ki-67 (MIB1) proliferation index is not an integral part of the current WHO classification of lung neuroendocrine tumors, it is of value, especially in the evaluation of small biopsy samples and cytologic specimens, when tissue is limited and poor preservation or extensive crush artifact during procurement may be inevitable. It has been suggested that Ki-67 (MIB1) percent positivity may be used as a diagnostic adjunct to morphologic

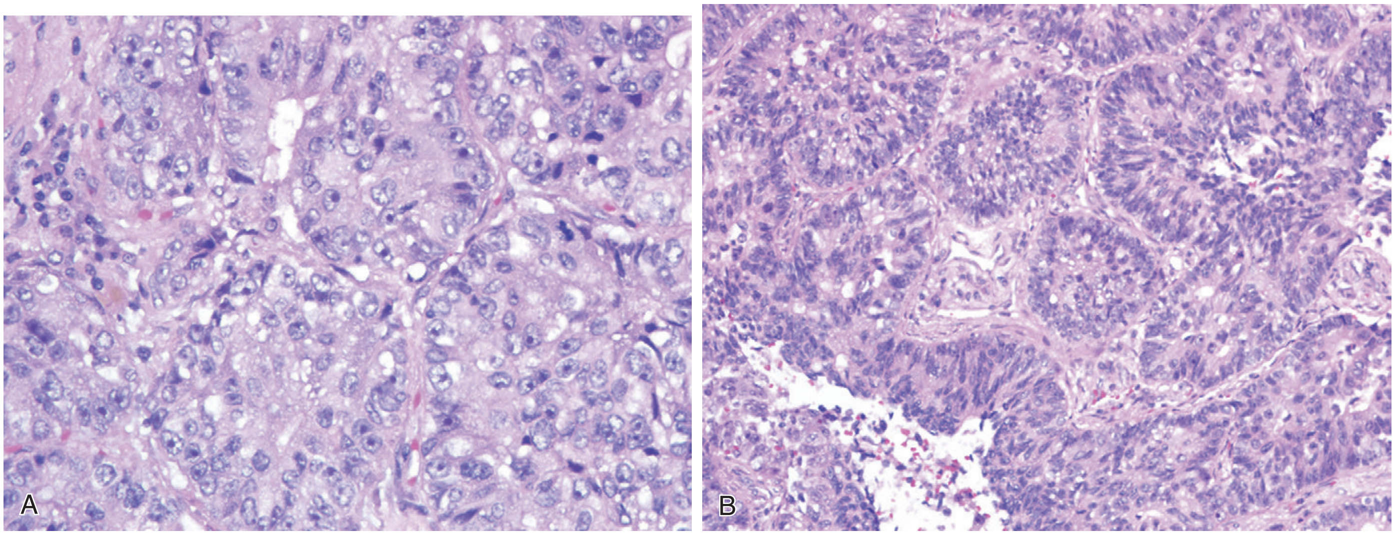

Figure 65-7 Large cell carcinoma. **A,** In this preparation, a high-grade pattern with prominent nucleoli is evident. (Hematoxylin-eosin stain, 40×.) **B,** On this specimen from a large cell neuroendocrine carcinoma, note the trabecular and nesting pattern of a neuroendocrine tumor. (Hematoxylin-eosin stain, 20×.)

examination: for typical carcinoid, less than 2%; for atypical carcinoid, less than 20%; and significantly, greater than 20% for small cell and large cell neuroendocrine carcinomas.

Traditionally, small cell carcinomas have been divided into limited-stage disease (treatable within a single radiation portal) and extensive-stage disease (contralateral or distant metastasis) with regard to prognosis. Recent large-scale analyses have shown the value of TNM staging for all neuroendocrine tumors of the lung, including carcinoid tumors.

Large Cell Carcinoma

By definition, *large cell carcinoma* of lung is an undifferentiated carcinoma lacking morphologic evidence of small cell carcinoma, squamous cell carcinoma, or adenocarcinoma. In other words, it represents a diagnosis of exclusion. These tumors typically are composed of sheets and nests of large polygonal cells with moderate amount of cytoplasm, vesicular chromatin and prominent nucleoli (Figure 65-7). Although the classification is purely based on morphologic grounds, judicious use of ancillary studies (as discussed previously), especially with small biopsy specimens, is of significant value in separating the poorly differentiated squamous cell carcinomas and adenocarcinomas from the truly undifferentiated large cell carcinoma. These tumors share similar demographic and clinical features with other non–small cell carcinomas of the lung, because they commonly are seen in elderly men with smoking history.

Large cell carcinomas are preferentially seen at the periphery of the lung. Several histologic subtypes are recognized: basaloid, clear cell, and lymphoepithelioma-like carcinomas. Although grouped under large cell carcinomas in the 2004 WHO classification, large cell neuroendocrine carcinoma, as strictly defined in the previous section, is best categorized as a neuroendocrine tumor, closely resembling small cell carcinoma. Nevertheless, the mere focal expression of neuroendocrine markers as detected on immunohistochemistry studies, seen in some large cell carcinomas, should not be interpreted as diagnostic for large cell neuroendocrine carcinoma. In general, large cell carcinomas are high-grade tumors that are similar in prognosis and pattern of spread to stage-matched non–small cell carcinomas, with performance status at the time of diagnosis and disease extension considered to be the most important clinical prognostic parameters. Metastases arise most commonly in the hilar and mediastinal nodes, followed by pleura, liver, bone, brain, abdominal nodes, and pericardium. The basaloid subtype carries a worse prognosis, even in the lower stages, with more common metastasis to the brain. On the other hand, lymphoepithelioma-like carcinomas generally are diagnosed at a later stage of disease but are associated with a better prognosis.

Pleural Malignancies

Diffuse malignant mesothelioma is a pleura-based cancer that may be histopathologically composed of a biphasic growth pattern of combined epithelial and sarcomatoid components. The tumor also may manifest in a monophasic form of either epithelioid cancer resembling a pleural adenocarcinoma or a spindle sarcomatoid form resembling a mesenchymal sarcoma. The diagnosis is usually but not exclusively rendered with a history of asbestos exposure, similar to that for pleural asbestosis or asbestos-related diseases and malignancies, but with a lower threshold of lung asbestos burden. Other proposed causes of diffuse malignant mesothelioma are chest radiation therapy and exposure to other mineral silicates, such as vermiculite and erionite. Erionite originally was identified in Turkey but is now appreciated to have widespread deposits in the western United States (i.e., Dakotas, Nevada, Arizona, and California). The diagnosis is based on appropriate clinical, radiographic, and histopathologic findings of a painful pleura-based tumor with scattered multiple nodules or a coalescent tumor encasing the lung. Malignant mesothelioma may obliterate the pleural cavity or be associated with an exudative pleural effusion. The tumor may invade the underlying lung and typically infiltrates through the diaphragm.

Malignant mesothelioma exhibits characteristic surgical pathology features that must be distinguished from reactive mesothelial proliferation and chronic fibrosing pleuritis. Reactive mesothelial hyperplasia frequently is present in the setting of collagen vascular diseases, drug or inflammatory reactions, and trauma or surgery. Of importance, reactive mesothelial hyperplasia lacks invasion of the stromal connective tissue and fat, does not undergo necrosis, and typically is not immunoreactive for EMA (epithelial membrane antigen) and p53 (tumor suppressor gene product). In the setting of exposure to asbestos, collagenous pleural plaques may be identified and associated with either reactive mesothelial hyperplasia or an incipient diffuse malignant mesothelioma. Separation of chronic pleuritis from malignant mesothelioma also is based on the lack of mesothelial invasion in pleuritis and the presence of an organizing zonal layered fibroinflammatory process. Desmoplastic malignant mesothelioma will, on the other hand, show stromal invasion, haphazard growth pattern, and metastatic spread. Reactive mesothelial cells and those of malignant mesothelioma are immunoreactive for cytokeratin. The histopathologic appearance of reactive mesothelial conditions is organized and layered, in contrast to the haphazard cellularity and invasion in malignant mesothelioma.

The histologic pattern of the epithelioid type of diffuse malignant mesothelioma appears as an invasive tubular and papillary malignancy that mimics a pleura-based adenocarcinoma or a metastatic adenocarcinoma. The monophasic sarcomatoid mesotheliomas resemble spindle cell sarcomas, which may manifest as primary or metastatic cancers. The most common form of malignant mesothelioma is the epithelioid variant and may show a variety of histologic features, such as tubulopapillary, glandular, or solid patterns. Cytologic examination of malignant pleural effusions shows irregular clusters of atypical mesothelial-like cells in pools of hyaluronic acid. Malignant mesotheliomas also may present in the peritoneal cavity and mimic ovarian cancers in women. Biphasic mesotheliomas are less common in the abdomen than in the pleura, and abdominal sarcomatoid mesotheliomas are rare. The distinction between malignant mesothelioma and adenocarcinoma in the pleura and peritoneal cavity is based on histologic features and supported by histochemical and immunohistochemical staining and ultrastructural findings. Mesotheliomas will be positive for Alcian blue, a stain that disappears with pretreatment with hyaluronidase. Most adenocarcinomas are histochemically positive for mucicarmine stains, although a few mesotheliomas also may stain positive. On immunohistochemical assays, malignant mesotheliomas will be immunoreactive for calretinin, keratin 5/6, WT-1 protein, and podoplanin (D2-40), in contrast with adenocarcinomas, which are immunoreactive for CEA (carcinoembryonic antigen), MOC-31, B72.3, Ber-EP4, and TTF-1. Both mesotheliomas and adenocarcinomas will be positive on assay for pancytokeratins, which will demonstrate the viability of the tissue for immunohistochemical assessments. Historically, the best diagnostic discriminator for distinguishing malignant mesothelioma from adenocarcinoma has been electron microscopic examination of the tumor. The ultrastructural appearance of malignant mesothelioma on transmission electron microscopy shows long slender microvillous processes with frequent branching and lacking a glycocalyx, in contrast with short blunt straight microvilli of adenocarcinoma, containing a glycocalyx.

MOLECULAR BIOLOGY

The study of cellular and molecular mechanisms of lung cancer has provided insight into lung cancer biology in terms of epidemiology and predisposition to lung cancer, lung cancer carcinogenesis, and cancer progression and resistance to chemotherapy and radiation therapy. Epidemiologic investigations have demonstrated higher levels of lung cancer in patients whose family history included a diagnosis of lung cancer in a first-degree relative. In a case-control study of lung cancer in women, never-smokers with positive family history had an odds ratio of 5.7 relative to nonsmokers without a family history. Smokers without a family history of lung cancer and smokers with a family history had odds ratios of approximately 15 and 30, respectively, for the development of lung cancer relative to non-smokers without a family history of lung cancer. Among persons who are carriers of a mutated retinoblastoma (*RB*) gene, the mortality rate for lung cancer is 15-fold that in the general population.

The cellular predisposition to lung cancer among cigarette smokers has included protean metabolic phenotypic pathways among smokers at risk for lung cancer. It appears clear that individual metabolism must play a role in carcinogenesis: The overwhelming majority of cancers are found in smokers, but among smokers, only a minority develop lung cancer. The host factors acting on environmental smoke metabolites include the pleiotropic expressions of the cytochrome p450 oxidative enzymes. Polycyclic aromatic hydrocarbons and nitrosamines, components of cigarette smoke and carcinogenic agents, induce the expression of P450 enzymes. In turn, cytochrome P450 metabolism produces reactive oxygenated intermediates that have the capacity for DNA binding and alterations, leading to mutations and cellular dysplasia. Aryl hydrocarbon hydroxylases, as members of the mixed-function oxidases, are induced by and active on cigarette smoke chemicals, and their metabolites are capable of causing DNA mutations and malignant transformation of cells.

One of the fundamental precepts of cancer development is multistep carcinogenesis involving basic steps of initiation (transmissible DNA damage leading to cellular dysplasia with altered regulatory controls), promotion (proliferation of abnormal cellular clones to form a mass), and progression (invasion and metastases). Cellular and molecular events that drive the conversion of preneoplastic conditions to malignant tumors are activations of cellular oncogenes, deletion or inactivation of tumor suppressor genes, enhancement of survival relative to apoptotic pathways, and alterations of DNA repair mechanisms. Early studies found chromosomal 3p deletions in lung cancers, more commonly in small cell carcinomas. *KRAS* activation and the expression of p21, involved in activation of cellular signal transduction pathways, have been identified in lung cancers. Mutations in *KRAS* were identified in adenocarcinomas, especially pronounced in smokers, and were associated with relatively poor survival. Genetic amplification and mutation of the *EGFR* gene, associated with increased or altered protein expression, have been identified predominantly in non–small cell carcinomas. Examples of inactivation of tumor suppressor genes are loss of Rb expression in some small cell carcinomas and inactivation of p53 in non–small cell carcinomas.

Molecular biology studies have provided insight into the initiation and progression of lung cancer. Additional investigations have revealed cellular and molecular changes that modulate the tumor's response to chemotherapy and provide acquired resistance to therapeutic management. Chemotherapeutic agents that act in the folate pathway of pyrimidine and DNA synthesis, such as pemetrexed, may demonstrate reduced efficacy when the functional level of thymidylate synthesis is overexpressed. Similarly, the overexpression of ERCC-1 (excision repair cross-complementation group 1), a repair enzymatic pathway for DNA strand breaks, modifies the therapeutic outcome with platinum drugs that intercalate in the DNA.

Tumors that appear to be markedly governed by a single or small set of pathway gene products are said to show "oncogene addiction." Despite the complexity of genetic and epigenetic tumor cell abnormalities, these "oncogene addiction" pathway genes dominate the progressive and invasive nature of the malignancy, and interruption of their function will lead to tumor regression, thereby promoting a prolonged disease-free interval or overall survival. This molecular condition provides the pharmacologic rationale for targeted therapy. The three genes discussed next appear to be in the "driver's seat" for tumor progression, and blocking their altered function will provide for tumor regression.

Epidermal Growth Factor Receptor Gene

EGFR is a transmembrane signaling protein that transduces extracellular signals, due to binding of EGFR ligands, into intracellular changes mediated by activating tyrosine kinase phosphorylations. EGFR, also called HER1 (human epidermal growth factor receptor 1), is in the same family as HER2, another membrane receptor that is amplified in approximately 20% of breast cancers. In breast cancer, HER2 is biologically associated with a relatively aggressive type of breast cancer, but it also is a therapeutic target for directed antibodies or small molecule tyrosine kinase inhibitors (TKIs). When EGFR is mutated, predominantly in nonsmokers, it adopts an activated state, as if constantly bound to activating ligands or growth factors. EGFR activation induces downstream signals that inhibit apoptosis and stimulate cell proliferation and migration and motility. Targeted TKIs are effective for tumor regression when non–small cell carcinomas have activating *EGFR* mutations, as opposed to tumors with wild-type *EGFR*. EGFR-activating mutations tend to be present in a minority of lung cancers (10% to 20%) and appear most commonly in nonmucinous adenocarcinomas exhibiting a well-differentiated acinar or papillary growth pattern with a lepidic growth margin and presenting demographically in younger Asian women who were never-smokers or light smokers. In this last demographic subgroup, the incidence of *EGFR* mutation may rise to 40% to 50%. Large cell carcinomas also have shown *EGFR* mutation; however, the rate of such mutations in squamous cell carcinoma is only a few percent, and this low frequency is not sufficient for routine analysis. Immunohistochemical identification of EGFR in tumor tissue has no correlation with clinical tumor response to TKIs. The *EGFR* mutation is the molecular marker, more significant than *EGFR* amplification, for targeted therapy and is a predictive factor for a therapeutic response. Fluorescence in situ hybridization (FISH) assays have been attempted to identify *EGFR* amplification and show some concordance with therapeutic response, because *EGFR* mutations correlate with amplification. Adenocarcinomas with nonmutated but amplified *EGFR* gene have been recognized, and these tumors show a partial response to tyrosine kinase inhibition.

The standard tests for *EGFR* mutations may be performed on formalin-fixed paraffin-embedded tissue and consist of direct DNA sequencing or mutation-specific assays investigating mutations that usually are found in exons 19 and 21. In instances of tumor recurrence due to resistance to TKIs, the sequencing analysis should be expanded to include exons 18 and 20. The acquired resistance tends to occur in about a year after TKI therapy is started and may be related to a new mutation in the active site; other causes for TKI resistance are due to *MET* gene amplification in 10% to 15% of cases. *EGFR* genetic testing shows concordant results with the presence of an activating mutation between the primary tumor and its metastasis in a majority of cases; however, an average discordance of 25%, as a result of tumor heterogeneity and progression, has been noted.

KRAS Oncogene

KRAS is an oncogene found on the short arm of chromosome 12 (12p) and shows mutations in approximately 20% of non–small cell lung cancers and amplification of the gene in a smaller set of cancers. The p21 protein (i.e., K-RAS), encoded by *KRAS*, couples with a cytoplasmic GTPase to convert guanosine triphosphate (GTP) to guanosine diphosphate (GDP) in order to modify transductive signals from the cytoplasm to the nucleus, thereby controlling cellular growth and survival pathways. When *KRAS* is mutated, GTP is maintained, and the signal is persistently in the "active" state. Activating mutations of *KRAS* are present in a variety of epithelial tumors, including colon and pancreatic cancers, and lead to activating phosphorylation of mitogen-activated protein kinase (MAPK), inducing nuclear signals of cellular proliferation and tumor progression. *KRAS* mutations and amplifications demonstrate clinicopathologic correlations with older age combined with male gender, history of heavy cigarette smoking, and advanced disease at presentation, with relatively aggressive tumors and poor clinical outcome. Histologically, *KRAS* mutations tend to be identified in poorly differentiated adenocarcinomas with solid growth pattern and lacking a lepidic growth pattern. Of interest, the mucinous lepidic pattern is associated with *KRAS* mutations. These high-grade adenocarcinomas also show lymphovascular invasion, mitotic activity, and tumor necrosis. K-RAS is downstream from EGFR effects and when activated is independent of EGFR status, thereby conveying resistance to tyrosine kinase inhibitors of EGFR function.

EML4/ALK

A new addition to molecular markers that predict a clinically favorable response to targeted therapy is the *EML4-ALK* translocation. The proper name of the fusion gene product is echinoderm microtubule-associated protein-like 4–anaplastic lymphoma kinase. The short arm of chromosome 2 (2p) may contain multiple small inversions and or translocations whose permutations generate in-frame fusions of the 5′ portion of the *EML4* gene with the 3′ end of the *ALK* gene, creating a chimeric tyrosine kinase with an intracellular kinase domain. Breakpoints of the *EML4* gene occur at several possible exon sites, although the breakpoint of the *ALK* gene tends to be specific for the kinase domain at exon 20. This fusion activation of the *ALK* gene is infrequent (occurring in less than 10% of non–small cell lung cancers), but the incidence may be enriched in lung cancers present in younger persons without significant smoking history in whom *EGFR* mutations and *KRAS* mutations are lacking. *EML4-ALK* translocations are histologically correlated with high-grade adenocarcinomas exhibiting acinar and solid growth patterns that contain mucinous and signet ring differentiation. From early studies, it appears that tyrosine kinase–targeted therapy for *EGFR* mutations is not effective treatment for *EML4-ALK* mutations. *EML4-ALK* fusion also appears to be selective for adenocarcinomas, because it is lacking in the other types of bronchogenic carcinomas.

The test for the translocation is based on reverse transcriptase–polymerase chain reaction (RT-PCR) assay of tumor tissue RNA, which amplifies and detects certain of the fusion constructs. The assay limitation is due to the identification of only the translocations of *EML4* exons 6 and 13 with *ALK* exon 20. The fusion gene also may be assayed by FISH techniques, and recent studies suggest that immunohistochemical methods also may yield accurate results.

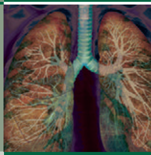
Section 12
LUNG TUMORS



Chapter 66
Lung Cancer: Clinical Evaluation and Staging

Lynn Tanoue

Every patient with lung cancer should undergo a timely and thorough clinical evaluation, starting with a comprehensive history and physical examination. The presence or absence of symptoms will influence subsequent imaging and invasive assessment, and decisions relating to future evaluation and treatment will be guided by the patient's overall health status, including comorbid medical conditions. This general assessment, ultimately leading to the determination of clinical stage, typically will inform further evaluation and will influence the choice of therapy. It is therefore critically important that this process be approached efficiently and comprehensively.

SYMPTOMATIC PRESENTATION

SYMPTOMS AND SIGNS RELATED TO THE PRIMARY TUMOR

Currently, most patients with lung cancer have advanced disease at the time of presentation and are likely to present with symptoms, particularly if local extension, metastasis to distant sites, or a paraneoplastic syndrome is present. Obtaining a thorough history and a review of systems in patients suspected of having lung cancer constitute an important part of the initial evaluation, because the symptom history will influence the choice of imaging studies, the interpretation of those studies, and the institution of early palliative interventions. Symptoms and signs related to the primary tumor most commonly include cough, dyspnea, chest pain, and hemoptysis. Cough is present in up to 75% of patients with lung cancer and may be related to airway involvement, postobstructive pneumonitis, or bronchorrhea. Dyspnea may be associated with primary site–related problems, such as endobronchial or extrinsic airway obstruction, postobstructive atelectasis, infection, or increased airway secretions, or may be related to metastatic disease, with potential manifestations including pleural effusion, lymphangitic tumor spread, pericardial effusion with tamponade, and pulmonary thromboemboli in the setting of hypercoagulability. Hemoptysis with lung cancer usually manifests as intermittent or persistent bloody streaking of the sputum and rarely can be massive. In up to 9% of patients with hemoptysis and lung cancer, the chest radiograph will be normal in appearance, underscoring the need to include endobronchial tumor as a major consideration in the differential diagnosis in patients presenting with hemoptysis and lung cancer risk factors (**Figure 66-1**). With the exception of hemoptysis, these pulmonary symptoms may not necessarily prompt a patient with a history of cigarette use, chronic obstructive pulmonary disease, or interstitial lung disease to seek specific medical attention or, conversely, for the clinician to consider an alternative diagnosis. These may be contributing factors to the consistent observation of a delay of several months between the onset of symptoms and a definitive diagnosis of lung cancer.

SYMPTOMS RELATED TO INTRATHORACIC SPREAD

Intrathoracic spread of lung cancer may occur by direct extension of the primary tumor or by involvement of lymph nodes and other thoracic structures. Chest pain is reported by up to 50% of patients at presentation and often indicates extension of tumor to the mediastinum, chest wall, or pleura. Hoarseness typically heralds involvement of the left recurrent laryngeal nerve, which in its circuitous course into the chest and under the aortic arch is particularly subject to compromise from left-sided cancers spreading to the ipsilateral mediastinal lymph nodes. Recurrent (inferior) laryngeal nerve palsy also may cause aspiration and coughing related to inadequate apposition of the vocal cords. Superior vena cava syndrome occurs more commonly with lung cancer than any other tumor, with small cell carcinoma the most commonly associated histologic subtype. Patients may present with a sensation of facial fullness, dyspnea, dysphagia, and headache or with actual swelling of the face, neck, and upper chest, and typically exhibit distended neck veins as well as a dilated venous pattern over the upper chest and shoulders. Superior sulcus (Pancoast) tumors are associated with a constellation of symptoms, primarily pain from compression or invasion of the brachial plexus (which, because it typically localizes to the shoulder and scapula, may not immediately prompt a pulmonary evaluation per se), Horner syndrome (ptosis, miosis, anhidrosis) due to involvement of the sympathetic chain and stellate ganglion, and upper extremity muscle wasting and pain related to tumor involvement of the eighth cervical and first and second thoracic nerve roots. Extension of tumor to the pericardium can result in pericardial effusion with or without tamponade, as well as arrhythmias. Bulky mediastinal adenopathy itself causes symptoms uncommonly, although dysphagia may result if the esophagus is compressed.

SYMPTOMS RELATED TO METASTATIC SPREAD

Lung cancer can spread distantly to any organ. The presence of constitutional symptoms, particularly weight loss but also fatigue, weakness, or poor appetite, and new symptoms

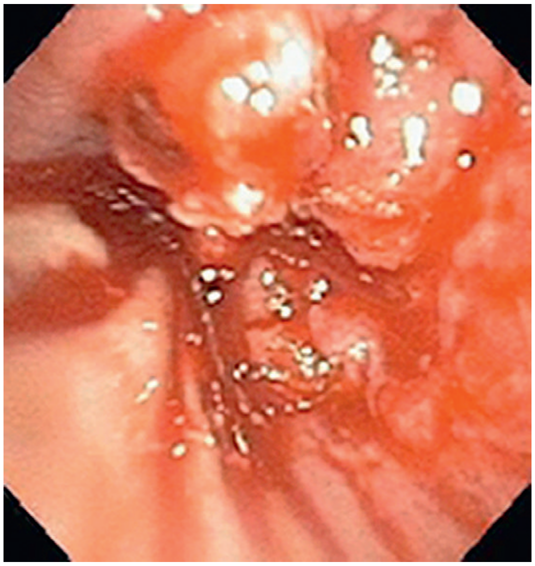


Figure 66-1 Endobronchial tumor in the left main bronchus, which manifested clinically as intermittent hemoptysis accelerating over the course of 2 months. *(Courtesy Jonathan Puchalski, MD.)*

related to any organ, including musculoskeletal pain, neurologic changes, hoarseness, and abdominal discomfort, should heighten the clinical suspicion for metastatic disease. Laboratory abnormalities, including anemia, abnormalities on liver function tests, and hypercalcemia, also should prompt a search for disease beyond the primary site. Conversely, the absence of any of these symptoms or signs on a thorough initial clinical assessment argues strongly against the presence of metastatic spread. The most common sites of distant spread are lymph glands, liver, bones, adrenal glands, brain and spinal cord, and pleura.

Lymph node metastases typically are seen first in the thorax, in either the ipsilateral hilar area or the mediastinum, and rarely cause symptoms. The supraclavicular fossa should be examined carefully in patients with known or suspected lung cancer, because this is the most common location for palpable malignant adenopathy and offers an easily accessible site for cytologic needle aspiration to establish diagnosis and stage of disease.

Liver metastases may be associated with constitutional symptoms including fever but usually are asymptomatic and often are not associated with any abnormalities on liver function tests. By contrast, bone metastases tend to manifest with pain and may be associated with elevations of alkaline phosphatase or serum calcium levels.

Adrenal metastases typically are unilateral but may be bilateral. Because most adrenal masses actually represent benign adenomas or hyperplasia, a more definitive noninvasive evaluation or biopsy is warranted. Adrenal metastases usually are asymptomatic; adrenal insufficiency related to metastatic invasion of the adrenal glands is rare.

The brain is a common site of spread in patients with lung cancer; conversely, a majority of brain metastases are related to primary sites located in the lung. Overall, intracranial metastasis is present in approximately 10% of all patients with lung cancer at initial diagnosis, with signs and symptoms ranging from headache and confusion to seizures or focal neurologic deficits.

Pleural involvement with tumor may take the form of pleural nodules, direct tumor extension, or malignant pleural effusion. Malignant effusions usually are exudative and may be either serous or bloody. Under the current staging system, the presence of a malignant effusion places the patient in a group with the most advanced stage of clinical disease (stage IV) and establishes nonresectability.

Table 66-1 **Paraneoplastic Syndromes Associated with Lung Cancer**

Endocrine	Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)/hyponatremia; hypercalcemia; ectopic adrenocorticotropic hormone (ACTH) syndrome; Cushing syndrome; hyperglycemia; hypoglycemia; hyperthyroidism; carcinoid syndrome; gynecomastia; elevated growth hormone; elevated follicle-stimulating hormone (FSH); galactorrhea
Musculoskeletal	Hypertrophic osteoarthropathy (HOP); clubbing, myopathy; dermatomyositis; polymyositis
Neurologic	Lambert-Eaton myasthenic syndrome (LEMS); encephalomyelitis/subacute sensory neuropathy; cerebellar degeneration; opsoclonus-myoclonus; autonomic neuropathy; retinopathy; mononeuritis multiplex; peripheral neuropathy; myopathy
Skin	Acanthosis nigricans; pruritus and urticaria, erythema multiforme; erythroderma; exfoliative dermatitis; hyperpigmentation
Hematologic	Anemia, thrombocytosis, leukocytosis, hypercoagulable state

Paraneoplastic Syndromes

Paraneoplastic syndromes occur in approximately 10% of patients with lung cancer (Table 66-1). Such syndromes may be the initial presenting complaint triggering an evaluation but also can develop late in the course of disease. Paraneoplastic syndromes are unrelated to direct invasion or distant spread of tumor and in and of themselves do not preclude curative-intent therapy. Endocrine syndromes associated with lung cancers often are characterized by tumor production of biologically active hormones. Lung cancer is the most common cause of cancer-associated hypercalcemia, hyponatremia, and syndromes involving ectopic production of adrenal corticotropic hormone (ACTH).

Hypercalcemia of malignancy is the most frequent of these syndromes and is seen most commonly in patients with squamous cell carcinoma. Hypercalcemia in lung cancer patients usually is related to the ectopic production of parathyroid hormone–related peptide (PTHrP), rather than to the osteolytic effects of bone metastases. Early symptoms—thirst, polyuria, fatigue, constipation, nausea—are nonspecific. Mental status changes, lethargy, and even coma may accompany more severe hypercalcemia. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) most commonly occurs in patients with small cell lung cancer (SCLC). In some SCLC series, hyponatremia related to SIADH is present in up to 10% to 15% of patients. As with hypercalcemia, the symptoms—weakness, nausea, headache—often are nonspecific; more severe hyponatremia may have serious consequences, including confusion, seizures, and coma. Ectopic ACTH syndrome is seen most commonly with SCLC. The classic features of Cushing syndrome—truncal obesity, myopathy and muscle weakness, diabetes, hypertension, hirsutism—often are absent. In most cases, tumor cells express a precursor hormone that is cleaved to ACTH. A minority of patients produce corticotropin-releasing hormone, which stimulates ACTH production in the pituitary. The distinction between these two processes can be determined by a dexamethasone suppression test.

Nonendocrinologic extrapulmonary syndromes include musculoskeletal abnormalities, most commonly asymptomatic digital clubbing, which can be seen in isolation or in the setting of hypertrophic pulmonary osteoarthropathy (HPO). The pathogenesis of HPO is unknown, but the disorder consists of a proliferative periostitis characterized by symmetric, painful arthropathy that typically involves the ankles, shins, knees, wrists, and elbows. The diagnosis usually is confirmed by the identification of new periosteal bone formation on plain radiographs of the long bones, or by demonstration of diffuse long bone uptake of radionuclide on bone scan or positron emission tomography (PET) imaging. HPO is more commonly seen with adenocarcinoma. Hematologic dyscrasias commonly occurring in patients with lung cancer include anemia, which may compound fatigue and dyspnea; thrombocytosis; and leukocytosis. Eosinophilia is seen only rarely. Lung cancer is the most common cause of hypercoagulability associated with malignancy, which usually declares itself as deep venous thrombosis or thromboembolism, or with classic Trousseau syndrome (migratory superficial thrombophlebitis). Lung cancer, and specifically SCLC, also is the most common cause of a clinically diverse group of paraneoplastic neurologic syndromes (see Table 66-1).

The commonality with several of these syndromes is that they appear to be driven by autoimmune mechanisms. The most common of these is the Lambert-Eaton myasthenic syndrome (LEMS), which occurs in approximately 2% to 4% of patients with SCLC. LEMS is characterized by proximal muscle weakness, hyporeflexia, dysarthria, blurred vision, and autonomic dysfunction. In contrast with myasthenia gravis, muscle strength typically does not improve with the administration of anticholinesterases, but some recovery of strength may be obtained with treatment of the underlying malignancy. LEMS is associated with an antibody that inhibits acetylcholine release by binding to calcium channels in peripheral cholinergic nerve terminals. The diagnosis usually is based on electromyography demonstrating small amplitude of the resting muscle action potential, which increases with repeated nerve stimulation or exercise. The syndrome of encephalomyelitis–subacute sensory neuropathy is associated with antineuronal nuclear-antibody types 1 and 2 (ANNA-1 and ANNA-2), also called anti-Hu and anti-Ri antibodies, respectively, which react with SCLC tumor cell surface proteins and with neuronal nuclear antigens. Anti-Hu antibodies also are seen in patients with SCLC and cerebellar degeneration as well as opsoclonus-myoclonus. Other paraneoplastic neuropathic syndromes include encephalomyelitis, autonomic neuropathy, and cancer-associated retinopathy.

ASYMPTOMATIC PRESENTATION

Approximately 25% of patients with lung cancer present at an early stage of their disease, so only a minority are asymptomatic at the time of diagnosis. The poor overall 5-year survival for patients with lung cancer reflects the disproportionate number of patients who are diagnosed at an advanced stage. Interest in establishing screening for early disease detection in asymptomatic patients has understandably been the focus of many studies. The reasons to develop a reliable lung cancer screening tool are quite evident. Most lung cancers are discovered because of symptom-driven evaluation; a diagnosis of advanced-stage disease unfortunately portends a limited prognosis. By contrast, asymptomatic patients with early-stage cancers are more likely to experience long-term survival with treatment.

Large studies performed since the 1970s evaluating chest radiography, sputum cytologic analysis, and low-radiation-dose chest computed tomography (CT) scanning for lung cancer screening have consistently demonstrated an increase in the number of lung cancers diagnosed and a shift toward identifying earlier-stage disease accompanied by an improvement in survival, but notably without a decrease in lung cancer mortality rates. The National Lung Screening Trial (NLST) is the first large-scale clinical trial to demonstrate a benefit in lung cancer mortality related to screening with low-dose chest CT scanning. The NLST enrolled 53,000 subjects aged 55 to 74 years who were current or former smokers with at least a 30 pack-year history, and who had no previous history of lung cancer. The study compared low-dose chest CT scanning and chest radiography as screening tools, with participants randomized to receiving three annual screens with one or the other modality, with follow-up over another 5 years. The trial was closed in late 2010 when initial results demonstrated that subjects assigned to the CT screening group had 20% less lung cancer deaths than those assigned to chest radiography screening. The disadvantages of screening include a high rate of false-positive findings, which incur additional diagnostic evaluation with the potential for risk or harm related to such evaluation; the anticipated high cost of screening and subsequent evaluation; and the potential consequences of cumulative exposure to radiation from multiple scans. The optimal approach to lung cancer screening inevitably will need to evolve over the coming years, as the results of the NLST are applied to clinical practice, and outcomes related to both benefit and disadvantages can be longitudinally examined.

THE SOLITARY PULMONARY NODULE

The typical presentation of an asymptomatic early stage lung cancer is as a solitary pulmonary nodule (SPN), defined as a solitary lesion 3 cm or less in diameter, surrounded by normal lung and not associated with other thoracic abnormalities such as hilar or mediastinal adenopathy, atelectasis, or pleural effusion. SPNs are common radiographic lesions, frequently identified as incidental findings on chest imaging studies done for issues unrelated to lung cancer. Typical scenarios include routine preoperative evaluation in which a lung nodule or mass is found on the plain chest radiograph, or is identified on a chest CT scan performed for screening purposes or for other reasons unrelated to any chest symptoms, and investigation featuring a CT scan of the abdomen, heart, or spine, in which a portion of the lungs is almost inevitably included.

In evaluating SPNs, it is useful to distinguish small (8 mm or less in diameter) from larger nodules. Small SPNs are very common findings in patients who have participated in CT screening studies for lung cancer, as well as in those undergoing CT scanning for non-lung-related reasons, as noted earlier. In the feasibility study for the NLST performed within the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, 21% of subjects had abnormalities identified on the baseline screening CT scan, most of which were small SPNs. Similarly, in the Mayo Clinic lung cancer screening study, 51% of subjects had abnormalities found on the baseline screening study, with an increase to 69% by the second annual screen, the vast majority of which were small SPNs. The enormous

Table 66-2 Fleischner Society Guidelines for Management of Small Pulmonary Nodules Detected on Computed Tomography (CT) Scans

Nodule Size*	Low-Risk Patient[†]	High-Risk Patient[‡]
≤4 mm	No follow-up needed[§]	Follow-up CT at 12 months; if unchanged, no further follow-up[¶]
>4-6 mm	Follow-up CT at 12 months; if unchanged, no further follow-up[¶]	Initial follow-up CT at 6-12 months, then at 18-24 months if no change[¶]
>6-8 mm	Initial follow-up CT at 6-12 months, then at 18-24 months if no change	Initial follow-up CT at 3-6 months, then at 9-12 months and 24 months if no change
>8 mm	Follow-up CT at around 3, 9, and 24 months, then dynamic contrast-enhanced CT, PET, and/or biopsy	Same as for low-risk patient

Note: Guidelines refer to newly detected indeterminate nodules in persons 35 years of age or older.

*Average of length and width.

[†] Minimal or absent history of smoking and of other known risk factors.

[‡] History of smoking or of other known risk factors.

[§] The risk of malignancy in this category (<1%) is substantially less than that determined with a baseline CT scan in an asymptomatic smoker.

[¶] Nonsolid (ground glass) or partly solid nodules may require longer follow-up period to exclude indolent adenocarcinoma.

PET, positron emission tomography.

Modified from MacMahon H, Austin JH, Gamsu G, et al: Guidelines for management of small pulmonary nodules detected on CT scans: a statement from the Fleischner Society, *Radiology* 237:395–400, 2005.

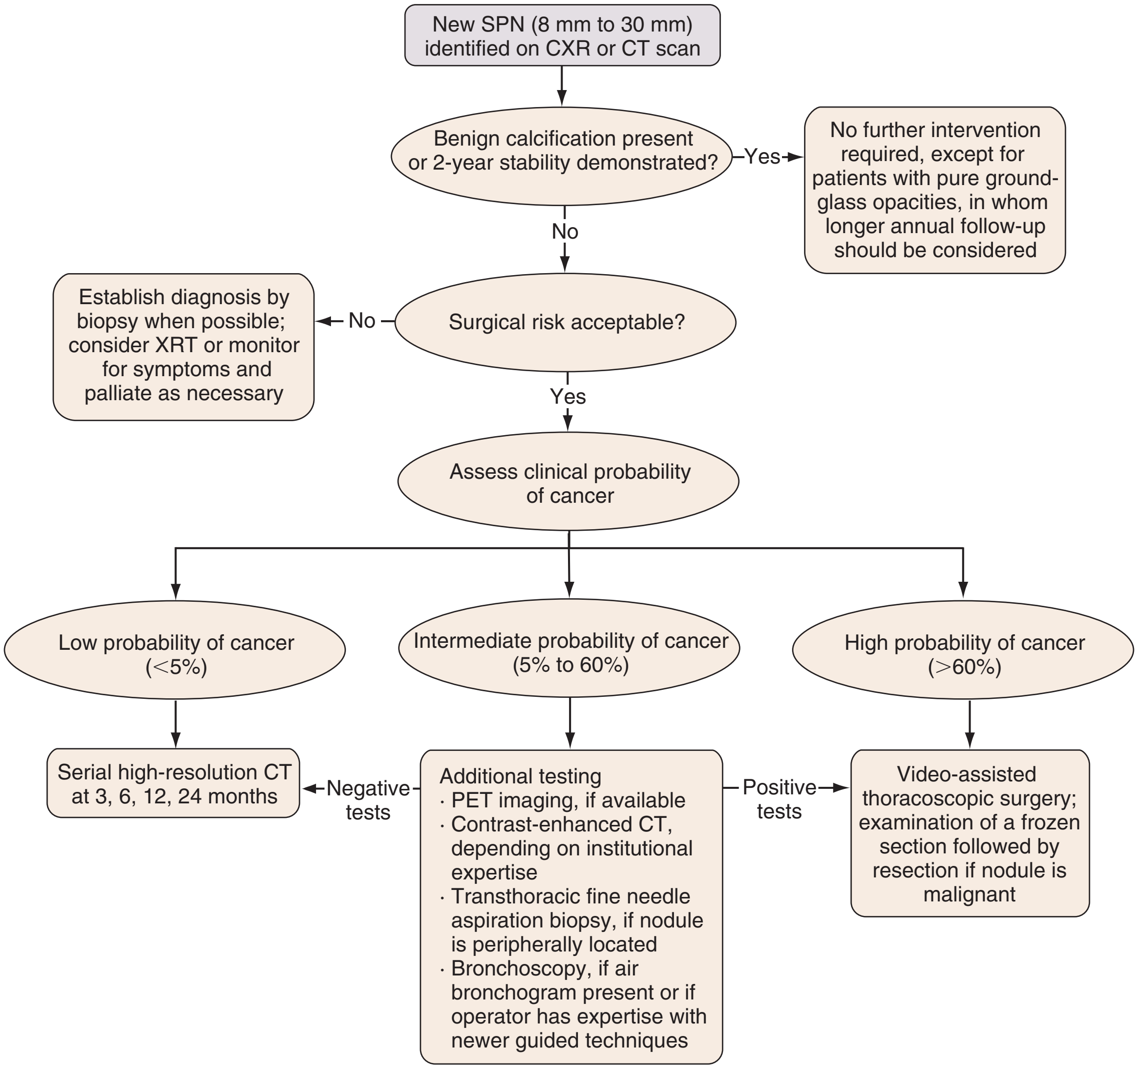
number of small SPNs generated by an increased volume of CT scanning prompted a position statement from the Fleischner Society proposing guidelines for the management of small (8 mm or less) SPNs detected on CT scans. The recommendations are outlined in Table 66-2. Appropriately applied, the guidelines outline algorithms for patients based on their risk of lung cancer, providing timelines for follow-up of incidentally discovered nodules that minimize the number of CT scans necessary in the course of evaluation. These practical recommendations will become even more relevant if CT screening for lung cancer becomes the standard of practice. Of note, these recommendations apply only to patients in whom SPNs are discovered incidentally, unrelated to any known underlying disease, and only for solid SPNs 8 mm or less in diameter. Specifically, the guidelines are not intended to apply to patients known to have or suspected of having malignant disease, patients younger than 35 years of age, or patients with unexplained fever. Furthermore, the recommendations are not fully applicable to persons with nonsolid (ground glass appearance) or partially solid nodules, who may require longer follow-up to permit exclusion of biologically indolent cancers with greater confidence.

Larger SPNs (8 to 30 mm) require further investigation. A review of any previous imaging studies should be the first step, because an established baseline can provide information important to the evaluation. A nodule that is identified as new or growing warrants clinical concern, whereas radiographic stability of a solid SPN over a 2-year period generally is considered to constitute reasonable evidence of benignity. The exception to this general rule is that it is increasingly evident that a 2-year period of stability is insufficient to allow confident designation of benignity for nodules that are purely of ground glass density. Other CT features also may reliably exclude malignancy, including the presence of fat identifying a hamartoma, complete or laminated calcification of the nodule, the presence of a feeding artery and a draining vein identifying a pulmonary arteriovenous malformation, the "comet tail" sign of swirling bronchovascular structures pointing to the hilum characteristic of rounded atelectasis, and the movement of a nodule within a cavity with positional changes characteristic of a mycetoma.

The larger the nodule, the more likely it is to be a cancer. A majority of asymptomatic pulmonary masses greater than 30 mm in diameter are malignant. Figure 66-2 outlines a management strategy for SPNs 8 to 30 mm in diameter recommended by the American College of Chest Physicians evidence-based clinical practice guidelines for lung cancer. The algorithm is appealing in its simplicity. The key step is the clinical definition of a pretest probability of malignancy for every patient with an SPN, because this will inform decisions about the extent of evaluation. SPN factors associated with malignancy include larger size, positive smoking history, older age, a previous history of cancer, the location within the lung (higher risk with upper lobe location), and nodule edge characteristics (higher risk with spiculated than with smooth borders) (Figure 66-3). Mathematical prediction models incorporating these factors typically perform similarly to the clinical acumen of experienced physicians. Patients with a low probability (less than 5%) of malignancy can be monitored by serial CT imaging. Patients with a high probability (more than 60%) of malignancy should proceed to definitive surgical biopsy or resection. For the large group of patients with an intermediate probability (5% to 60%) of malignancy, the use of a variety of noninvasive and invasive modalities should be considered in deciding whether the SPN should be observed, biopsied, or removed.

Noninvasive imaging modalities commonly used to evaluate SPNs include CT and PET imaging. As already described, certain CT features may establish a benign diagnosis or support the rationale for a period of watchful waiting. By contrast, other findings may more strongly suggest malignancy, including spiculated nodule borders, a dilated bronchus leading into the nodule, and cavitation associated with a thick and irregular wall. CT with dynamic contrast enhancement, in which the demonstration of an increase in Hounsfield units with the administration of contrast is associated with a higher likelihood of malignancy, may be useful in institutions with proficiency in this technique. PET scanning with 18-fluorodeoxyglucose (FDG) is increasingly utilized in the characterization of SPNs. Increased glycolysis is a well-described metabolic characteristic of malignant cells, resulting in enhanced uptake of glucose and FDG. FDG accumulates in these cells because it cannot be completely metabolized.

In SPNs greater than 10 mm in diameter, the sensitivity of PET for identifying malignancy is high (80% to 100%), although specificity is less robust. PET is less sensitive for nodules measuring less than 10 mm in diameter, and its use for evaluating the likelihood of malignancy in small nodules should be discouraged. This modality may yield false-positive results in the setting of inflammation or infection, including tuberculosis, fungal infections, rheumatoid nodules, and sarcoidosis, all of which may mimic lung cancer radiographically. False-negative findings typically are described for patients with well-differentiated tumors, including adenocarcinoma in situ (bronchioloalveolar carcinoma) and carcinoid tumors, for which the tumor metabolic rate presumably is low. PET may be most useful in a situation in



New SPN (8 mm to 30 mm) identified on CXR or CT scan
Benign calcification present or 2-year stability demonstrated?
Yes
No further intervention required, except for patients with pure ground-glass opacities, in whom longer annual follow-up should be considered
No
Surgical risk acceptable?
No
Establish diagnosis by biopsy when possible; consider XRT or monitor for symptoms and palliate as necessary
Yes
Assess clinical probability of cancer
Low probability of cancer (<5%)
Intermediate probability of cancer (5% to 60%)
High probability of cancer (>60%)
Serial high-resolution CT at 3, 6, 12, 24 months
Negative tests
Additional testing
· PET imaging, if available
· Contrast-enhanced CT, depending on institutional expertise
· Transthoracic fine needle aspiration biopsy, if nodule is peripherally located
· Bronchoscopy, if air bronchogram present or if operator has expertise with newer guided techniques
Positive tests
Video-assisted thoracoscopic surgery; examination of a frozen section followed by resection if nodule is malignant

Figure 66-2 Management algorithm for patients with solitary pulmonary nodules (SPNs) 8 to 30 mm in diameter. *CT*, computed tomography; *CXR*, chest radiograph; *PET*, positron emission tomography; *XRT*, radiotherapy. *(From Gould MK, Fletcher J, Iannettoni MD, et al: Evaluation of patients with pulmonary nodules: when is it lung cancer?* Chest *132:108S–130S, 2007.)*

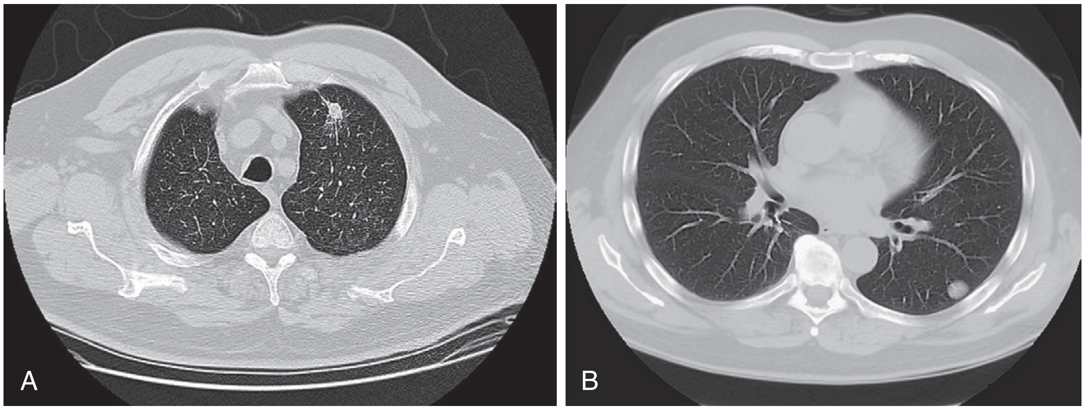


Figure 66-3 Asymptomatic solitary pulmonary nodules visualized on computed tomography. **A,** A 12-mm left upper lobe nodule with spiculated borders in a 74-year-old man with a 50 pack-year smoking history. Surgical resection revealed adenocarcinoma, pT1aN0M0, stage Ia. **B,** A 14-mm left lower lobe nodule with smooth border in a 64-year-old man who was a lifelong nonsmoker. Histopathologic/cytologic evaluation revealed a hamartoma.

which the clinical suspicion for malignancy is low despite suggestive CT findings; in this case, a positive result on PET scanning would lower the threshold to pursue some type of invasive evaluation, whereas a negative result would add reassurance regarding a period of observation.

Invasive modalities of assessing SPNs include surgical removal, bronchoscopic biopsy or aspiration, and percutaneous transthoracic needle aspiration (TTNA). For asymptomatic patients in whom the clinical pretest probability of malignancy is very high and for whom the risk of surgery is acceptable, a strong argument can be made to proceed directly to surgical resection, because this strategy would offer the most efficient, albeit most invasive, approach to establishing a diagnosis and stage, while also potentially providing definitive therapy. In many situations, however, a limited nonsurgical biopsy may be warranted—for example, in patients in whom a benign diagnosis is a strong consideration and a nonsurgical biopsy may potentially be definitive (e.g., tuberculosis or hamartoma), patients in whom surgical resection carries a high risk for complications, and patients who are unwilling to accept a surgical approach without at least an initial attempt to establish a definitive diagnosis. Before bronchoscopy or TTNA is undertaken, a discussion should be held with the patient regarding the possible outcomes, and in particular to consider the approach to be taken should the biopsy be nondiagnostic. This discussion is of particular importance, because a definitive benign diagnosis often is difficult to establish with these procedures, which frequently provide limited biopsy material. Bronchoscopic biopsy has a reasonable diagnostic yield (55%) in nodules greater than 20 mm in diameter, with the yield increasing as nodule size increases and if radiographic evidence of a bronchus leading into the nodule ("bronchus sign") is present. For peripheral nodules less than 20 mm, the diagnostic yield with bronchoscopy is considerably lower, in the range of 10% to 50%, which may be increased by incorporating radial ultrasound or electromagnetic navigational technology to enhance accurate localization.

Percutaneous TTNA commonly is performed under CT or fluoroscopic guidance, with improved diagnostic capability when a core needle biopsy is done in addition to aspiration. TTNA typically is considered for SPN evaluation when bronchoscopy is unlikely to render a diagnosis, usually for SPNs that are relatively small (less than 20 mm) and peripherally located. The diagnostic yield of TTNA for malignant lesions is higher (up to 85%) in studies in which the prevalence of malignancy is high and nodule size is 20 to 40 mm. For smaller nodules, the yield falls, with nondiagnostic biopsy samples obtained in up to 41% of patients with SPNs less than 40 mm in diameter, and in particular when the lesion is benign. The major drawback of TTNA is a high rate of pneumothorax (10% to 35%). Approximately 5% of procedures are complicated by pneumothorax of enough clinical significance to warrant placement of a chest tube. TTNA may pose a higher risk in situations in which the lung traversed by the needle en route to the lesion is emphysematous or bullous, or in patients who are unable to hold their breath as directed during the procedure.

LUNG CANCER STAGING

Staging is an essential and critical part of the management of every patient suspected of having or diagnosed with lung cancer. The staging classifications of the American Joint Committee on Cancer for non–small cell lung cancer (NSCLC) and SCLC now both follow the tumor-node-metastasis (TNM) system. The current seventh edition, published in 2010, was developed by the International Association for the Study of Lung Cancer (IASLC) using an international database of over 80,000 lung cancer cases. The distribution of database cases informing the staging classification spanned four continents: Europe 58%, North America 21%, Asia 14%, and Australia 7%. Although the database still included a majority of white patients and thus may be limited in application to nonwhite patient populations, the magnitude and diversity of the IASLC database constituted a remarkable improvement over the previous lung cancer staging system, which had been developed in a largely single-institution North American patient cohort.

Table 66-3 Designations for Types of Staging Assessments

Prefix	Name	Definition
c	Clinical	Before initiation of any treatment, using any and all information available (e.g., including mediastinoscopy)
p	Pathologic	After resection, based on pathologic assessment
y	Restaging	After part or all of the treatment has been given
r	Recurrence	Stage at time of a recurrence
a	Autopsy	Stage as determined at autopsy

From Detterbeck FC, Boffa DJ, Tanoue LT: The new lung cancer staging system, *Chest* 136:260–271, 2009.

Table 66-4 Staging Designation for Completeness of Surgical Resection

Symbol	Name	Definition
R0	No residual	No identifiable tumor remaining; negative surgical margins
R1	Microscopic residual	Microscopically positive margins but no visible tumor remaining
R2	Gross residual	Gross (visible or palpable) tumor remaining

From Detterbeck FC, Boffa DJ, Tanoue LT: The new lung cancer staging system, *Chest* 136:260–271, 2009.

SCLC previously was staged according to the Veterans Administration Lung Cancer Study Group (VALSG) two-stage system. In this system, "limited-stage" disease refers to cancer confined to one hemithorax, which may include the ipsilateral lymph nodes. From a practical perspective, a limited-stage SCLC is confined to an area that can be encompassed in a single radiation treatment field. "Extensive-stage" SCLC includes any tumor extending beyond the confines of limited-stage disease, including tumor confined to one hemithorax but involving the pleura. Although this two-stage system is no longer the official staging system for SCLC, it is still clinically appealing in its relatively easy application to treatment planning.

Different types of staging may be used to describe a malignancy during a course of evaluation (Table 66-3). The most common staging assessments are the *clinical stage* (indicated by the prefix c), defined as the stage before treatment as determined by all available imaging and biopsy data, and the *pathologic stage* (indicated by the prefix p), defined as the stage determined on the basis of the available imaging and biopsy data, as well as analysis of tissue samples obtained after a surgical resection performed with intent to cure. The completeness of resection is determined histopathologically after surgery (Table 66-4). Clinical staging typically is associated with poorer outcomes than those achieved with pathologic staging, the latter being inherently more accurate. All patients will undergo clinical staging; only in a select number will their disease be able to be staged pathologically. Restaging may take place after treatment, at the time of a recurrence, or at autopsy, identified by the prefix y, r, or a, respectively, as outlined in Table 66-3.

Table 66-5 Definitions for Tumor-Node-Metastasis Descriptors

Descriptor			Definition	Subgroups[*]
T			***Primary tumor***	
	T0		No primary tumor	
	T1		Tumor ≤3 cm,[†] surrounded by lung or visceral pleura, not more proximal than the lobar bronchus	
		T1a	Tumor ≤2 cm[†]	T1a
		T1b	Tumor >2 but ≤3 cm[†]	T1b
	T2		Tumor >3 but ≤7 cm[†] or tumor with any of the following[‡]: invades visceral pleura, involves main bronchus ≥2 cm distal to the carina, atelectasis/obstructive pneumonia extending to hilum but not involving the entire lung	
		T2a	Tumor >3 but ≤5 cm[†]	T2a
		T2b	Tumor >5 but ≤7 cm[†]	T2b
	T3		Tumor >7 cm;	$T3_{>7}$
			or directly invading chest wall, diaphragm, phrenic nerve, mediastinal pleura, or parietal pericardium;	$T3_{Inv}$
			or tumor in the main bronchus <2 cm distal to the carina[§];	$T3_{Centr}$
			or atelectasis/obstructive pneumonitis of entire lung;	$T3_{Centr}$
			or separate tumor nodules in the same lobe	$T3_{Satell}$
	T4		Tumor of any size with invasion of heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina;	$T4_{Inv}$
			or separate tumor nodules in a different ipsilateral lobe	$T4_{IpsiNod}$
N			***Regional lymph nodes***	
	N0		No regional node metastasis	
	N1		Metastasis in ipsilateral peribronchial and/or perihilar lymph nodes and intrapulmonary nodes, including involvement by direct extension	
	N2		Metastasis in ipsilateral mediastinal and/or subcarinal lymph nodes	
	N3		Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph nodes	
M			***Distant metastasis***	
	M0		No distant metastasis	
	M1a		Separate tumor nodules in a contralateral lobe;	$M1a_{ContrNod}$
			or tumor with pleural nodules or malignant pleural dissemination[‖]	$M1a_{PlDissem}$
	M1b		Distant metastasis	M1b
Special Situations				
TX, NX, MX			T, N, or M status not able to be assessed	
Tis			Focus of in situ cancer	Tis
T1[§]			Superficial spreading tumor of any size but confined to the wall of the trachea or main bronchus	$T1_{SS}$

[*] These subgroup labels are not defined in the IASLC publications but are added here to facilitate a clear discussion.
[†] In the greatest dimension.
[‡] T2 tumors with these features are classified as T2a if diameter is 5 cm or less.
[§] The uncommon superficial spreading tumor in central airways is classified as T1.
[‖] Pleural effusions are excluded that are cytologically negative, nonbloody, transudative, and clinically judged not to be due to cancer.
From Detterbeck FC, Boffa DJ, Tanoue LT: The new lung cancer staging system, *Chest* 136:260–271, 2009.

The TNM paradigm is based solely on anatomy (Table 66-5). The T descriptor characterizes the primary tumor, the N descriptor, involvement of the regional lymph nodes; and the M descriptor, the presence or absence of distant metastases. Combinations of these descriptors are grouped into stages. Even though limitations to the generalized application of the TNM system are increasingly appreciated, it serves as a consistent structure to describe extent of disease and to provide prognosis. Furthermore, staging provides a platform for comparisons between reasonably homogeneous populations in therapeutic clinical trials. It may be tempting to use the clinical stage as the major determinant of therapy, but it is important to recognize that the staging classification system is not intended to be an algorithm for assigning treatment. The designation of stage inherently portends prognosis, because the separation of TNM combinations into stages is fundamentally determined by survival. Two of the limitations of the TNM system become immediately evident. First, the anatomic descriptors yield no

information relating to biologic behavior of the cancer. With a burgeoning recognition that the molecular characteristics of an individual tumor may drive outcomes and more specifically render some tumors very responsive to targeted treatments, the prognostic ability of the TNM system becomes less reliable. Second, patients who share similar survival outcomes may have clinically dissimilar cancers; this divergence becomes clear on examining the stage groupings outlined in Table 66-6. Within a given stage of disease, the patients often are not clinically homogeneous, even though they may have similar survival rates. Despite the large size of the IASLC database, outcomes for specific TNM groups with small numbers of patients could not be adequately evaluated, with an inevitable "lumping" rather than "splitting" of these groups. Other issues remain unresolved with use of the current system, including how to incorporate specific radiographic features such as the density of pulmonary nodules, or how to properly prognosticate in clinical situations that fall out of the staging paradigm, for example, the presence of multiple synchronous primary tumors, but the most important limitation is the absence of components reflecting tumor biology. As current understanding of molecular pathways important to neoplasia expands, it seems inevitable that the staging system must incorporate such information in the future.

Ultimately, even with its limitations, the current staging classification represents a major advance in lung cancer care, providing a reliable language to facilitate consistent description and communication, and to give patients, their families, and their physicians insight regarding prognosis. The tools and strategies applied most commonly in the process of clinical evaluation are discussed in the following sections within the context of their use in defining the separate clinical stages.

STAGE I

In the IASLC database, 28% of patients with NSCLC presented with stage I disease. Patients with stage IA lung cancer (T1aN0M0, T1bN0M0) are those with malignant solitary pulmonary nodules 3 cm or less in diameter. These patients typically are asymptomatic. In general, the smaller the SPN, the less likely spread will have occurred beyond the primary site. CT scan should be performed in all patients with known or suspected lung cancer, with inclusion of the upper abdomen for evaluation of the liver and adrenal glands, because these are common sites of metastasis. By definition, CT scanning in stage I disease will not demonstrate enlarged hilar or mediastinal nodes.

In a systematic review of the medical literature performed to inform the American College of Chest Physicians evidence-based guidelines for the diagnosis and management of lung cancer (5111 total evaluable patients with a median prevalence of mediastinal metastasis of 28%), the pooled sensitivity and specificity of CT scanning for identifying mediastinal lymph node metastasis were 51% and 86%, respectively. In the specific clinical situation combining an SPN 3 cm or less and a normal-appearing mediastinum on chest CT, the likelihood of finding malignant mediastinal lymph node involvement by surgical lymph node sampling is low, approximately 6%. Whether this small percentage justifies further noninvasive staging beyond CT scanning is controversial. Overall, PET gives false-negative results in approximately 20% of patients with lung cancer associated with normal-sized but malignant mediastinal nodes. The decision of whether or not to pursue PET imaging must take this into consideration, as well as the possibility that identifying a false-positive abnormality may trigger unnecessary evaluation. Similarly, brain magnetic resonance imaging (MRI) and CT scanning are of low yield in general in patients with lung cancer in whom findings on clinical examination are normal (0 to 10%), and particularly so in patients with clinical stage I NSCLC. Conversely, patients with symptoms suggesting distant disease should undergo further noninvasive imaging, even though the primary tumor may be small.

Patients with stage IB lung cancer have larger solitary tumors (ranging from less than 3 cm to more than 5 cm in diameter). In such cases, the primary tumor may be surrounded by normal lung but also may invade the visceral pleura, involve the main bronchus 2 cm or more distal to the carina, or be associated with atelectasis or obstructive pneumonia not involving the entire lung. The likelihood of finding regional nodal or distant metastasis in the setting of a larger primary lesion is higher than in stage IA, so these patients should undergo PET scanning and brain imaging (MRI or CT with contrast) as part of their staging evaluation (Figure 66-4). With the recognition that false-positive results on PET are frequent with nonmalignant inflammation or infection, tissue confirmation should be obtained whenever possible to establish the presence or absence of regional or distant metastasis, because patients should not be denied potentially curative treatments on the basis of imaging alone. Conversely, controversy continues regarding whether a negative result on PET scan in a patient with a T2 or T3 solitary pulmonary lesion and normal mediastinal nodes on CT scan should be followed by tissue biopsy to prove that the mediastinum is truly free of disease. In a metaanalysis evaluating this question, the probability of finding malignant lymph node involvement when both CT and PET findings were negative was approximately 9% (of note, the pretest probability of mediastinal lymph node metastasis was estimated at 35%, and

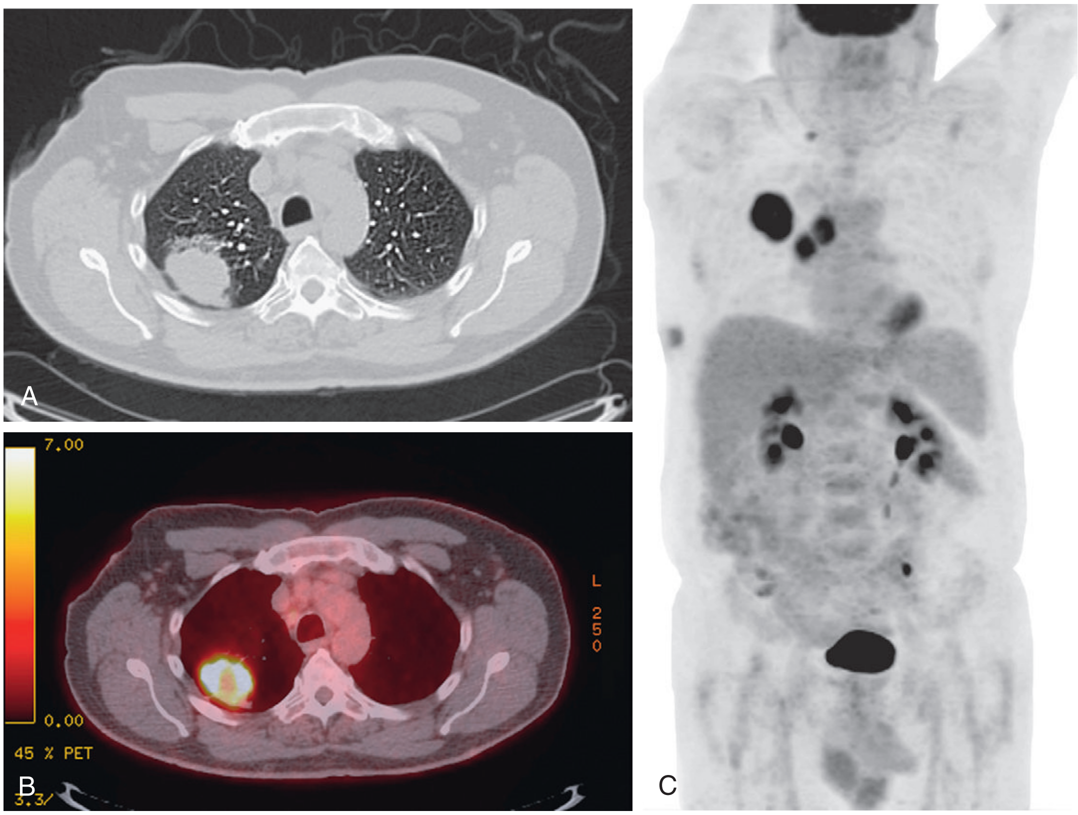

Figure 66-4 The patient was a 69-year-old man with a 45 pack-year smoking history who presented with cough. **A,** Chest computed tomography (CT) scan demonstrates a 4.8-cm right upper lobe mass. The hila and mediastinum appeared normal. **B,** Fused transaxial positron emission tomography (PET) image at the same level as in **A** demonstrates intense fluorodeoxyglucose (FDG) uptake in the right upper lobe mass. **C,** Coronal PET image demonstrates intense FDG uptake in the right upper lobe mass as well as in the right hilum and the mediastinum. Brain magnetic resonance imaging (MRI) was negative. Mediastinoscopy demonstrated adenocarcinoma. Clinical stage was T2aN2M0, stage IIIa.

patients were not differentiated by the size of the primary tumor). Clinicians ultimately must decide whether the overall 9% probability of mediastinal lymph node metastasis in patients with clinical stage IB disease and negative results on CT and PET imaging of the mediastinum warrants further invasive evaluation. This decision may be influenced by the recognition that certain subgroups, including patients with central or larger tumors, have an increased likelihood of mediastinal nodal involvement.

STAGE II

Stage II encompasses a variety of TNM groupings, including those comprising patients who have large lung masses that may invade local structures, patients with small primary tumors and hilar nodal involvement, and patients whose tumors have an endobronchial component within 2 cm of but not involving the main carina. The range of T descriptors in stage II emphasizes that the stage designations are defined by survival outcome, not by anatomy alone. Clinical staging for patients with stage II disease parallels that for stage IB, because the evaluative process typically must include a decision about whether to pursue an invasive mediastinal examination in the setting of negative results of mediastinal imaging on chest CT. Patients with stage II disease are more likely to have occult mediastinal lymph node (N2) involvement, so PET scanning should be routinely included in their staging assessment. The hilar (N1) nodes are difficult to biopsy, except perhaps by a bronchoscopic approach under endobronchial ultrasound (EBUS) guidance. If the ipsilateral N1 nodes are enlarged on CT scan or demonstrate FDG uptake on PET imaging, it usually is not necessary to sample them before surgery, because they will be removed at the time of resection. However, N1 involvement increases the likelihood that N2 nodes also are involved, even if CT and PET results are negative, and in such cases, invasive evaluation of the mediastinum should be performed to evaluate for the possibility of higher-stage disease. Because by definition the mediastinal nodes in this case are not enlarged, a focused evaluation will not be possible. Accordingly, the most complete mediastinal evaluation possible should be pursued, which may vary institutionally, with preferential use of mediastinoscopy, EBUS, or EBUS with endoscopic ultrasound (EUS).

MRI is not frequently indicated in the evaluation of patients with lung cancer, with the notable exception of patients in whom a more accurate evaluation relating to the bones of the chest cage, the soft tissues and vasculature, or the brachial plexus (in the setting of a superior sulcus [Pancoast] tumor) is necessary. Patients with stage II lung cancer defined by large primary tumors invading adjacent structures often fall into these categories. In these challenging clinical situations, MRI may be superior to CT scanning in distinguishing neoplastic from normal tissues.

STAGE III

Approximately one third of patients with lung cancer present with clinical stage III disease. All patients with evidence of stage III disease on chest CT scan should be evaluated for the presence of distant disease; this may be accomplished by a combination of (1) brain MRI or head CT and (2) PET imaging or abdominal CT scanning with bone scan. The presence of metastatic disease immediately changes the clinical stage to IV. As

Figure 66-5 The International Association for the Study of Lung Cancer lymph node map. *(From Rusch VW, Asamura H, Watanabe H, et al: The IASLC Lung Cancer Staging Project: a proposal for a new international lymph node map in the forthcoming 7th edition of the TNM classification for lung cancer,* J Thorac Oncol *4:568–577, 2009.)*

with stage II, stage III comprises a wide variety of TNM groupings (see Table 66-6). However, a majority and perhaps the most clinically challenging of these patients with such disease will be defined by involvement of the N2 nodes; careful evaluation of the mediastinum is thus vitally important. The IASLC lymph node map defining the lymph node stations is shown in Figure 66-5.

Mediastinal Evaluation: Noninvasive Modalities

Chest CT remains the most accurate anatomic modality for evaluation of the mediastinum. Pathologic enlargement of the mediastinal nodes is defined as a short-axis diameter of 1 cm or greater. CT in the setting of lung cancer is a relatively inaccurate tool for identification of malignant involvement in the mediastinum. Many studies evaluating CT accuracy in this setting have demonstrated that approximately 20% of mediastinal nodes that are not enlarged are actually malignant; conversely, approximately 40% of enlarged mediastinal nodes are actually benign. For all patients with enlarged discrete mediastinal lymph nodes on CT, further evaluation of the mediastinum should be performed before a definitive treatment decision is reached, in view of the high false-positive rate. The exception to this approach would be in patients with bulky mediastinal disease, with lymph node infiltration around vessels and airways so extensive that discrete lymph node measurements are meaningless (Figure 66-6). In such cases, malignant involvement of the nodes would be assumed, and the establishment of cell type could be pursued by sampling the most accessible site, either the mediastinal nodes or the primary tumor.

PET scanning is recommended for further evaluation of all patients with clinical stage III lung cancer because of the high likelihood of distant disease. PET scanning is now widely available, with utilization of this modality markedly increasing over the past decade. Abdominal CT with bone scan is a reasonable substitute if PET is unavailable. PET is superior to CT with respect to evaluation of the mediastinum. In a large systematic review including 2865 evaluable patients with lung cancer, the pooled sensitivity and specificity of PET for identifying mediastinal lymph node metastasis were 74% and 85%, respectively. In a separate metaanalysis of patients with enlarged mediastinal lymph nodes, the median sensitivity and specificity of PET were reported at 100% and 78%, respectively. Thus, PET is superior to CT in identifying malignant mediastinal lymph nodes, but approximately 20% of nodes identified as abnormal by PET imaging are actually benign, reflecting the fact that tissues other than cancer can exhibit increased cellular glucose uptake. Because malignant N2 nodal involvement may be the critical factor determining whether a patient is surgically resectable, it is important that tissue confirmation be obtained whenever possible before making a final determination of clinical stage.

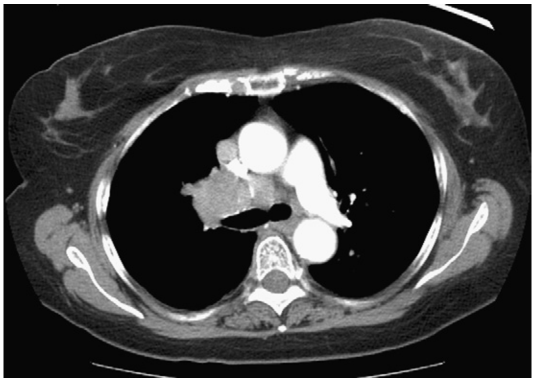

Figure 66-6 The patient was a 62-year-old woman with a 30 pack-year smoking history who presented with cough. Chest computed tomography (CT) reveals a right upper lobe mass with extension of tumor into the mediastinum and precarinal mediastinal adenopathy. Bronchoscopy with endobronchial ultrasound imaging demonstrated endobronchial invasion of tumor at the level of the main carina; biopsy specimens confirmed adenocarcinoma. There was no evidence of distant metastasis. Clinical stage was T4N2M0, stage IIIb.

Table 66-7 **Mediastinal Lymph Node Stations: Accessibility to Minimally Invasive Modalities**

Procedure	Accessible Mediastinal Lymph Node Stations
Mediastinoscopy	Stations 2, 3, 4, 7 (anterior only)
Extended cervical mediastinoscopy	Station 6
Video-assisted thorascopic surgery (VATS)	Ipsilateral stations 2, 3, 4, 7; station 6 with left-sided procedure
Parasternal mediastinotomy (Chamberlain procedure)	Station 5 (aortopulmonary window)
Endobronchial ultrasound (EBUS)	Stations 2, 3, 4, 7
Endoscopic ultrasound (EUS)	Stations 4, 5, 7, 8, 9
Transthoracic needle aspiration (TTNA)	All stations

Mediastinal Evaluation: Invasive Modalities

A variety of minimally invasive modalities are available for the evaluation of the mediastinal lymph nodes (Table 66-7). TTNA, EUS, extended cervical mediastinoscopy, and EBUS typically are utilized for the purpose of directed biopsy in patients with discrete abnormalities on CT or PET scanning. The choice between these procedures will be decided by the anatomic location of the abnormal nodes and by institutional expertise. The sensitivities of all of the directed minimally invasive techniques are very high, in part because they typically are done in situations in which the prevalence of malignancy in the abnormal nodes also is very high. In theory, all mediastinal lymph nodes are amenable to TTNA, although the individual anatomy will determine whether biopsy is feasible. Ultrasound-guided biopsy techniques using endoscopy or bronchoscopy are increasingly available and have high diagnostic yield.

The specific advantage of EUS is the capability of sampling station 8 and station 9 nodes in the inferior mediastinum, the potential to gain access to subdiaphragmatic structures including the celiac nodes and the adrenal glands, and in some cases the ability to sample the aortopulmonary window (station 5) nodes. Anterior mediastinotomy (Chamberlain procedure) is perhaps the most reliable method for reaching station 5 nodes. EUS is limited in that it cannot reach nodes anterior to the trachea. EBUS allows bronchoscopic access to the pulmonary parenchyma, to nodes in both hila, and to nodes anterior to the trachea as well as in the subcarinal space, affording the opportunity to sample the primary tumor as well as N1 and N2 nodes in a single procedure.

For patients who have no evidence of mediastinal adenopathy on noninvasive imaging, a more comprehensive examination of the mediastinal lymph nodes can be accomplished by mediastinoscopy, EBUS with or without EUS, or video-assisted thorascopic surgery (VATS), with the choice between these procedures largely decided by institutional expertise. Mediastinoscopy has long been considered the "gold standard," although it is imperfect. The superior mediastinal nodes (stations 1 to 4) and the anterior portion of the subcarinal space (station 7) are typically accessible to mediastinoscopy, but the posterior subcarinal space, the aortopulmonary window (station 5), and paraaortic nodes (station 6) are not. The station 6 nodes are the hardest to sample by any means other than surgery (VATS or open thoracotomy). In centers with focused expertise, EBUS performs as well as mediastinoscopy for evaluation of the radiographically negative mediastinum, particularly if combined with EUS. EBUS allows sampling of all nodal stations accessible to standard mediastinoscopy, with the advantage of the ability to access the posterior subcarinal space, inspect the airway for endobronchial lesions, and potentially sample the primary site as well. The addition of EUS to EBUS affords the potential for the most extensive examination of the mediastinum, while providing the opportunity to also sample structures below the diaphragm.

The most invasive approach to mediastinal evaluation is surgical lymphadenectomy. The aortopulmonary window and the paraaortic nodes (stations 5 and 6) may be particularly difficult to access with minimally invasive techniques, and in such cases a surgical approach may be necessary. Both VATS and open thoracotomy offer the opportunity to extensively sample the mediastinum but usually are limited to the ipsilateral nodes. These procedures uncommonly are performed for the sole purpose of examining the mediastinum, with lymph node sampling more typically pursued as an adjunct to resection of the primary tumor. VATS may have the additional benefit of the opportunity to visualize the pleural space, which may be important in a patient with pleural effusion and negative findings on pleural fluid cytologic examination, or to evaluate other abnormalities seen on imaging studies, such as separate pulmonary or pleural nodules or pleural thickening.

STAGE IV

Stage IV lung cancer is defined by the presence of any distant (M1) site of disease. The initial evaluation of any patient with suspected lung cancer should include a thorough history and physical examination and a basic laboratory evaluation. The presence of abnormalities on this initial evaluation is associated with a high likelihood of finding metastatic disease. Constitutional symptoms (e.g., unintentional weight loss, unexplained fevers), focal symptoms (e.g., localized pain, bone pain, unexplained headaches, focal neurologic symptoms) or signs (e.g., hoarseness, hepatomegaly, soft tissue masses), or laboratory abnormalities (e.g., unexplained anemia, hypercalcemia, liver

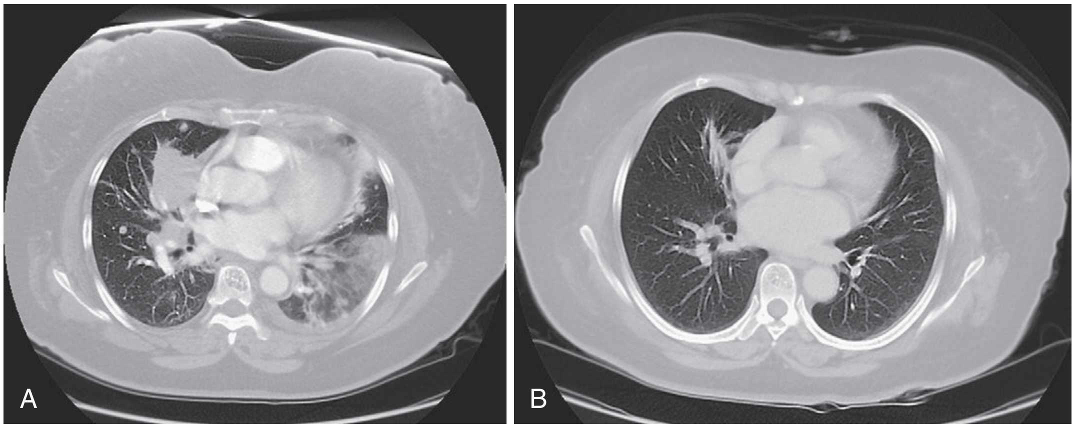

Figure 66-7 The patient was a 66-year-old Asian woman, a lifelong nonsmoker who presented with progressive dyspnea over the course of several weeks. **A,** Chest computed tomography (CT) scan demonstrates a 4-cm mass in the right middle lobe with right hilar adenopathy and multiple bilateral pulmonary nodules. Also evident is mediastinal adenopathy. A palpable right supraclavicular lymph node was biopsied, demonstrating adenocarcinoma. Mutational analysis revealed a deletion in exon 19 of the *EGFR* gene. Clinical stage was T2aN3M1, stage IV. **B,** Chest CT scan obtained in the same patient after 6 weeks of treatment with erlotinib. Marked decrease in the size of the right middle lobe mass with resolution of satellite nodules is evident.

function test abnormalities) should trigger an investigation directed by the specific finding. In such cases, comprehensive imaging is indicated regardless of the size of the primary tumor. All patients with known or suspected lung cancer should undergo chest CT scanning, preferably inclusive of the upper abdomen. Asymptomatic patients whose CT abnormalities indicate a higher likelihood of metastases (e.g., N1 or N2 nodal enlargement, pleural effusion, nodule in a separate ipsilateral or contralateral lobe) should also undergo further noninvasive evaluation. As noted for patients with stage III disease, a complete noninvasive evaluation may consist of (1) brain MRI or head CT plus (2) PET imaging or abdominal CT scan with bone scan. Arguably, all patients suspected of harboring M1 disease should undergo these imaging studies, because prophylactic palliation of asymptomatic sites in organs such as brain or bone may preserve quality of life. However, patients with obvious metastases, such as palpable soft tissue masses, bulky adenopathy outside the thorax, or obvious tumor infiltration in the liver, may not necessarily require further imaging, because spread of disease is clear. In patients in whom the clinical picture is highly suggestive of M1 disease, tissue confirmation at the metastatic site, if feasible, would provide the most efficient means of establishing both diagnosis and stage.

The most common sites of lung cancer metastasis are the brain, adrenal glands, bones, and liver, although any site may be involved. Brain MRI and head CT with contrast are equally sensitive in identifying patients with brain metastases, although MRI is more likely to detect multiple lesions. PET scanning or abdominal CT with contrast in combination with radionuclide bone scan (plus the original chest CT) are suitable for examination of the rest of the body. PET imaging has the advantage of being a single whole-body study; abnormalities seen on the original chest CT study also can be reevaluated for the presence of abnormal metabolic activity.

Two metastatic situations warrant specific mention. The adrenal glands are a common site of lung cancer spread; they also are common sites for benign adenomas, which are found in approximately 3% to 9% of the general population. MRI may be helpful in distinguishing a benign adrenal adenoma from adrenal metastasis. Tissue confirmation of a questionable adrenal nodule may be warranted, particularly if it is the sole potential metastatic site, because resection of an isolated oligometastasis in the adrenal gland (or brain) in a patient with surgically approachable primary disease can be associated with improved long-term survival. Management of pleural disease also can be challenging in a patient with otherwise resectable lung cancer. One of the major differences between the current and previous editions of the lung cancer staging system is in the designation of pleural dissemination, and particularly malignant pleural effusion, as M1a. Pleural effusions in lung cancer patients can arise for many reasons other than malignant involvement, including parapneumonic effusion in the setting of postobstructive pneumonia and effusions associated with congestive heart failure and pulmonary embolism. Up to 14% of ipsilateral pleural effusions in patients with lung cancer are found to be benign. The sensitivity of pleural fluid cytologic testing for detection of malignancy is approximately 60%, increasing to 85% with three thoracenteses. This approach is not sufficiently sensitive to be reliable when clinical suspicion for pleural dissemination is high but the cytologic findings, even with repeated thoracenteses, are negative. In such cases, pleuroscopy or thoracoscopy should be performed for direct visual inspection of the pleural surfaces, to exclude malignant pleural involvement as definitively as possible before curative-intent surgery is performed for the primary lesion.

FUTURE DIRECTIONS

Even with the many advances accomplished in its newest edition, the current staging system is imperfect. Its most obvious deficiencies are a lack of incorporation of information related to tumor cell type and the absence of any indicators of biologic behavior. It is increasingly evident that distinguishing between cell types within the NSCLC classification is important in identifying populations of patients for the purposes of comparing clinical outcomes, for defining homogeneous groups of patients for clinical trials, and ultimately for assigning treatment. It also is clear that molecular profiling of cancers can play an important role in characterizing subgroups of patients who share common gene mutations or translocations that may drive the neoplastic process, particularly in never-smokers or light smokers with lung adenocarcinoma (Figure 66-7). In the future, these distinctions are likely to help define new staging classifications incorporating indicators of biologic activity, with the potential for effectively facilitating personalized patient care.

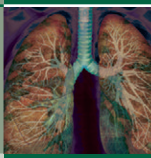
Section 12
LUNG TUMORS



Chapter 67
Lung Cancer: Treatment

Douglas Arenberg

Lung cancer is one of the most common solid tumors, particularly in industrialized nations, with an incidence similar to breast, colon, and prostate cancer. However, lung cancer accounts for more deaths than all these other cancers combined because of the inherent, often-aggressive biology of lung cancer; the nature of the lung itself, which can readily harbor an advanced tumor in the absence of symptoms; the poor response to treatment; and until recently the lack of an effective screening test.

As with many cancers, therapy for lung cancer includes surgery, chemotherapy, and radiation therapy, either alone or in combination. Definitive treatment increasingly includes combinations of two or all three of these modalities. Improved understanding of the molecular basis of cancer has led to treatments exploiting specific molecular abnormalities (targeted therapy). Lung cancer treatment has become more complex over time, in part because of recognition of tumor-specific and patient-specific traits that predict a greater likelihood of success, or lack of success, with specific drugs. This evolution of "personalized" cancer treatment should not overshadow the following principles of lung cancer treatment, which have remained largely constant over time:

1. Curative therapy should be used whenever feasible.
2. Curative therapy must address all grossly detectable disease, as well as reduce the likelihood of death from occult metastatic disease.
3. Toxicity or risk from treatment can outweigh the benefit when the patient is burdened by significant comorbid illness or when the risk of distant metastasis is extremely low.

Two competing principles are often cited as well: the treatment of lung cancer is strictly dependent on the stage of the disease, but accurate staging is often not possible before treatment (surgery) is rendered. This apparent paradox is resolved by recognizing that the first step in evaluating a patient with suspected lung cancer is the simultaneous determination of (a) whether cancer is the likely diagnosis on clinical grounds, (b) if cancer, whether it appears surgically resectable for cure, and (c) if "yes" to the first two questions, whether the patient can tolerate the required degree of surgical resection (see Chapter 66).

In the subset of patients for whom the answer to all three questions is "yes," surgery is often the next step, and accurate pathologic staging of the disease is determined after complete resection. For patients in whom surgery is not feasible because of locally advanced or metastatic disease, or because of physiologic comorbidity, a biopsy that provides *both* a diagnosis and an accurate staging is necessary. For these patients, the appropriate treatments are chemotherapy and radiotherapy, either alone or in combination, depending on the stage and the likelihood of distant metastasis. However, a significant percentage of patients with advanced disease will be too sick to treat because of a poor performance status or extensive comorbidity.

This chapter divides lung cancer treatment on the basis of tumor anatomy (or staging) and patient physiology (or "performance status"). The following discussion of treatment by *stage* is restricted to non–small cell lung cancer (NSCLC); small cell lung cancer (SCLC) is considered in a separate section.

NON-SMALL CELL LUNG CANCER

STAGE I LUNG CANCER

Stage I disease in NSCLC is completely confined to the lung parenchyma or airway, without nodal spread, and does not arise within 2 cm of the carina. The standard of care for patients with adequate lung function, no other significant comorbid illness (e.g., unstable coronary artery disease, debilitating arthritis), and a nodule with high probability of being lung cancer is surgical resection. Patients with stage I NSCLC who undergo surgery with complete resection of their disease have a high rate of cure with surgery alone (60%-80%).

Based on a randomized trial of NSCLC surgery conducted by the Lung Cancer Study Group, *lobectomy* is the standard surgery for lung cancer. Beginning in 1982, this study compared outcomes of patients who underwent lobectomy versus segmentectomy or wedge resection. The rate of local recurrence was 75% lower in the lobectomy group, and since then, lobectomy has remained the "gold standard" procedure for healthy patients with stage I disease.

Recent data and advances in imaging have led to a reevaluation of this standard. Specifically, several Japanese studies showed that small (≤2 cm) peripheral tumors with a ground-glass appearance on thin-section computed tomography (CT; ≤3 mm) had a low rate of nodal involvement, with 5-year survival of almost 100%, even after limited anatomic resection. Newer studies are re-addressing the appropriate degree of lung resection for patients with small, stage I tumors. One should also bear in mind that the time frame of the Lung Cancer Study Group trial comparing limited resection with lobectomy predated the widespread use of CT and positron emission tomography (PET) scans. Also, the increased use of CT scans to image the chest results in more tumors being detected at smaller sizes. This smaller average size of tumors should not be interpreted to justify abandoning lobectomy as a standard of care, but randomized controlled trials (RCTs) designed to determine the optimum degree of resection in this more modern setting are ongoing.

For now, the standard procedure for stage I NSCLC remains a lobectomy with lymph node dissection. Exceptions to this rule are usually applied for patients with peripheral tumors and limited pulmonary reserve from emphysema. Many surgeons will offer limited pulmonary resection, with or without concomitant *lung volume reduction surgery* (LVRS), to patients with severe emphysema. Published series demonstrating the feasibility of LVRS for patients with severe emphysema universally came from groups participating in RCTs of LVRS. This cannot be overlooked as a contribution to the better-than-expected outcomes in these highly select patients. Patients undergoing evaluation for LVRS who also had lung cancer surgery underwent rigorous pulmonary rehabilitation, with surgery in centers with regimented postoperative pain management, early mobilization, chest physiotherapy, and bronchodilator treatment. Lung cancer surgery for patients with severe emphysema should be done in centers with experience in all these strategies. Preoperative staging of these patients must be thorough, to avoid incomplete resection of tumors with nodal metastases.

The presence or absence of *nodal involvement* is the most important prognostic factor to determine after surgical resection. In addition to lobectomy, mediastinal lymph node dissection is essential to accurate staging of surgically resected lung cancer and must be done as part of any lung cancer resection. Some studies have found a direct correlation between survival and the number of lymph nodes removed at surgery, although this has not been widely validated.

The surgical approach to NSCLC has traditionally employed posterolateral thoracotomy as the standard procedure. The development of video-assisted thoracoscopic surgery (VATS) in the 1990s, followed by its spread through thoracic surgical training programs, has gradually resulted in a greater proportion of NSCLC surgeries being performed by this approach. Various studies show that VATS lobectomy is oncologically equivalent to open lobectomy, such that the tumor-containing lobe is removed intact, and mediastinal lymph node dissection or sampling is completed with equal effectiveness by either approach. VATS lobectomy is associated with less incision pain, reduced length of stay, and faster recovery of preoperative activity levels than open lobectomy. These advantages make VATS the approach of choice for most lobectomies, allowing well-trained thoracic surgeons to offer lobectomy to patients with a broader range of comorbid conditions.

Some patients are not candidates for VATS lobectomy, and occasionally an operation started with the VATS approach is converted to an open procedure at the surgeon's discretion. The open approach is more suited to large (>3 cm) tumors or central tumors located close to the major blood vessels or airway. Patients with these tumors may benefit from the surgeon's greater tactile access in an open chest to ensure resection margins are negative and arteries and airways are removed intact. In addition, patients who have had preoperative chemotherapy or radiation, or who have pleural adhesions or prior chest surgery, may not be candidates for VATS. Tumors with chest wall invasion requiring an en bloc resection usually require an open approach as well. When pneumonectomy is required for complete resection, it is generally performed by thoracotomy. In such situations the size of the specimen requires a large incision to facilitate removal of the specimen, reducing the advantages of VATS.

In general, centers that treat the largest number of patients have the best survival outcomes, for all treatment modalities, but especially for the surgical resection of lung cancer. In the United States, approximately 80% of lung cancer resections between 1996 and 2005 were performed by surgeons for whom lung cancer surgery was not the primary focus of their practice. In this same study, thoracic surgeons (those for whom noncardiac thoracic surgery was the primary focus of their practice) had the lowest operative mortality for patients requiring lobectomy or pneumonectomy. Current evidence-based guidelines from the American College of Chest Physicians (ACCP) advocates that patients being considered for lung cancer surgery should be seen by a "thoracic surgical oncologist with a prominent part of his/her practice focused on NSCLC."

For patients with pathologically confirmed stage I disease, postoperative chemotherapy (adjuvant therapy) is not currently the standard of care. Based on RCT results of postoperative chemotherapy, patients with completely resected, pathologic stage I disease did not have a clear survival benefit with adjuvant chemotherapy. Subgroup analysis of RCTs suggests that patients with the highest risk (based on current understanding of such risk) may benefit from adjuvant therapy. These patients were generally those with large (>4 cm) primary tumors. Many oncologists offer discussions of risks and benefits of adjuvant chemotherapy to patients with large, stage IB tumors (>4 cm) or those with other possible risk factors, such as prominent vascular invasion. On an individualized basis, this practice is reasonable, but adjuvant chemotherapy cannot yet be considered the standard of care for completely resected stage I NSCLC.

For patients with clinical stage I NSCLC who are not candidates for resection because of comorbidity, there are still curative options, and the current standard of care is external beam radiation. An extensive discussion of radiotherapy methods is beyond the scope of this text, but the trend in thoracic oncology for inoperable stage I disease has been toward *stereotactic body radiotherapy* (SBRT) and away from conventionally fractionated *external beam radiotherapy* (EBRT). Conventional radiotherapy is given in doses of 60 to 70 grays (Gy), usually divided into 30 fractions of 2 to 2.5 Gy. SBRT is a form of radiotherapy employing many customized lower-dose beams converging into a volume that encompasses the tumor. These treatments are usually given up to a dose of 50 to 60 Gy over 3 to 5 days of treatment. Tumor motion caused by respiratory excursion can be significant, leading to undertreatment of tumor and overexposure of normal tissue to radiation, if the motion of the tumor is not tracked accurately. SBRT can be delivered more accurately with the use of fiducial markers placed in or near the tumor to track it during the respiratory cycle.

Cure rates with SBRT in stage I NSCLC for patients carefully staged can be excellent; 3-year disease-free survival in a large Phase II trial was close to 50%, with most recurrences being distant disease. Patients with large or centrally located tumors are more likely to be treated with conventionally fractionated EBRT; toxicity was greater in those with central tumors in a Phase II study of SBRT. Some groups treating large numbers of patients with SBRT report late development of chest wall pain or rib fractures. The risk factors for rib fracture include tumors within 2 cm of the chest wall and larger treatment volume. Complications in patients treated with SBRT should be tracked closely because it is a relatively new modality used in this patient population.

Thermal ablation is a minimally invasive therapy that can be used for local control of primary lung tumors. *Radiofrequency ablation* (RFA) uses a radiofrequency probe inserted percutaneously into the tumor, usually under CT guidance, to generate frictional heating that leads to cell death. RFA is the most frequently performed thermal ablation procedure used to treat lung tumors. Although the role of RFA is not clearly defined in lung cancer, small uncontrolled case series support its use for lung metastases. Although RFA is performed more often to treat hepatic and renal tumors, it may be well suited to the lung because of its ability to concentrate thermal energy focally within tumor tissue, with little or no energy spreading to the adjacent aerated normal lung parenchyma. There are no RCTs comparing RFA with radiotherapy in medically inoperable patients.

Based on published data, smaller tumors (<3 cm) may be more effectively treated with RFA than larger tumors. Peripheral tumors surrounded by lung parenchyma and away from hilar structures can be safely treated with RFA. The risk of pneumothorax is significant, as high as 50% in one series. Because this is a newer technology, the role for RFA in treating lung cancer has not been defined by large, well-controlled studies, but centers with experience in this approach can offer this option for inoperable patients, particularly if there is a contraindication to radiotherapy, such as prior irradiation.

A point of emphasis is necessary for defining the term “unresectable” stage I disease. In general, the most qualified person to determine a given patient’s suitability for surgery is an experienced thoracic surgeon with lung cancer as a major focus of practice. The benefits of surgery are being extended to more patients with more severe comorbid conditions because of improvements in preoperative care, surgical techniques, and postoperative care. Patients with severe COPD or other comorbid illnesses should not be denied surgery without at least seeing an experienced thoracic surgeon. Furthermore, decisions about any patient’s operability should be made in the context of optimum therapy for underlying lung disease.

In some patients a trial of bronchodilators and inhaled or oral corticosteroids might result in improvement in lung function sufficient to reduce surgical risk. The nature of these patients and the increased use of multimodality treatment across all stages of NSCLC make a compelling rationale for a multidisciplinary approach to treating patients with lung cancer.

STAGE II LUNG CANCER

Stage II NSCLC is defined as including mainly (1) tumors with hilar or intralobar nodal metastasis, with tumor confined to one lobe of the lung, or (2) tumors invading the chest wall, without nodal metastasis. Treatment of stage II NSCLC is still primarily surgical resection, and the same principles apply here as in stage I disease. One major difference is that adjuvant chemotherapy has proven survival benefit for patients with stage II disease. If one makes the safe assumption that the risk of systemic chemotherapy is the same whether the patient had stage I or stage II disease, then the favorable risk/benefit data for adjuvant chemotherapy in patients with stage II reflects that occult metastases are more likely to be present in patients with more advanced disease. Therefore, patients with pathologic stage II lung cancer have more to gain with adjuvant chemotherapy than stage I patients. After recovery from surgery, patients who undergo surgical resection of tumors with peribronchial or hilar nodal metastasis (stage II NSCLC) should be referred to a medical oncologist to discuss adjuvant chemotherapy.

Current recommendations suggest all patients with stage II or III disease should receive postoperative chemotherapy. However, metaanalyses of adjuvant trials suggest the number of patients who need to be treated with adjuvant chemotherapy to achieve one additional long-term cure is 24 to 39. To reduce this number, studies looked for additional patient or tumor-specific characteristics that predict benefit (or lack of) from adjuvant treatment. One oft-cited study found tumor biomarkers that may identify patients most likely to benefit from adjuvant chemotherapy. Retrospective examination of tumor specimens from patients enrolled in an adjuvant trial identified *excision repair cross complementation* 1 (ERCC1), an enzyme involved in repairing cisplatin-induced DNA damage, as a possible prognostic and predictive marker. High expression of ERCC1 was associated with a good prognosis, but also identified a patient subgroup who did not benefit from adjuvant (cisplatin-based) chemotherapy. Similarly, high expression of *ribonucleotide reductase* M1 (RRM1, which metabolizes gemcitabine) was identified by immunohistochemistry as predicting better overall survival, but poor response to gemcitabine-containing chemotherapy. Insufficient data are available to recommend the use of biomarker-based selection of any chemotherapy, including adjuvant chemotherapy, but studies are underway to determine whether this improves outcomes relative to empirically chosen chemotherapy and allows fewer patients to be treated while achieving the same survival benefit.

Postoperative radiotherapy for completely resected stage II NSCLC does not have proven survival benefit, may be associated with worse outcomes, and in general should not be used. However, for patients with stage II NSCLC who *cannot tolerate* surgical resection, definitive radiotherapy is the standard of care. Although radiotherapy can provide excellent local control rates, it does not reduce the likelihood of distant metastasis. An unanswered question is whether adjuvant chemotherapy would benefit patients with clinical stage II NSCLC treated with curative radiotherapy. If adjuvant chemotherapy reduces the likelihood of death after surgery for stage II disease, the same approach might benefit patients treated with radiotherapy. No data support this approach, however, and extrapolating surgical data to patients treated with radiotherapy for local control is not appropriate outside of a clinical trial.

STAGE III LUNG CANCER

Stage III NSCLC makes up the largest proportion of any stage and generally includes patients with mediastinal nodal metastasis. Historically, the treatment for stage III lung cancer was thoracic radiotherapy alone, but long-term survival with this approach was poor (<10%), with most patients succumbing to distant metastases. Studies showed that combining systemic chemotherapy with thoracic radiation could improve long-term survival to close to 20%.

The current standard of care for adequately staged patients with stage III NSCLC depends greatly on the patient’s comorbid conditions and overall health status. The most commonly used global assessment of these factors in clinical practice is *performance status* (**Box 67-1**). Standard treatments for those with good to excellent Eastern Cooperative Oncology Group performance status (ECOG 0-1) are chemoradiation therapy administered concurrently. For those with less favorable performance status (ECOG 2), sequential chemotherapy followed by radiation therapy is still possible. The rationale for this is that concurrent therapy provides a survival benefit compared with sequential therapy, but at the cost of a greater likelihood of toxicity. Pulmonary toxicity is similar whether treatment is concurrent or sequential, but the occurrence of esophagitis (which can be severe) is more common with concurrent chemoradiation therapy than with sequential therapy. Those with marginal performance status (ECOG 2) may tolerate sequential therapy but are poor candidates for concurrent chemotherapy with thoracic radiation. In general, patients with ECOG performance status 3 or worse are best treated with a palliative approach focused on managing symptoms (i.e., best supportive care). This can include local radiotherapy to minimize complications such as airway obstruction, chest wall pain, or hemoptysis. Patients with poor performance status do not benefit from systemic chemotherapy and are more likely to experience severe toxicity.

Box 67-1 ECOG Performance Status Scale*

0: Asymptomatic (fully active, able to carry on all activity without restriction)
1: Symptomatic but completely ambulatory (restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature; e.g., light housework, office work)
2: Symptomatic, <50% time in bed or chair during the day (ambulatory and capable of all self-care but unable to carry out any work activities)
3: Symptomatic, >50% of time spent in bed or chair, but not bedbound (capable of only limited self-care)
4: Bedbound (completely disabled; cannot carry on any self-care; totally confined to bed or chair)
5: Death

From Oken MM et al: Toxicity and response criteria of the Eastern Cooperative Oncology Group, *Am J Clin Oncol* 5:649–655, 1982.
*Eastern Cooperative Oncology Group; also referred to as the World Health Organization (WHO) or Zubrod scale.
Use of performance status scales is central to the oncologist's assessment of both the likelihood of efficacy and the risk of toxicity of systemic chemotherapy.

The choice of chemotherapy for stage III NSCLC includes a platinum-based drug (cisplatin or carboplatinum) in combination with one other agent with demonstrated activity in NSCLC (Table 67-1). *Gemcitabine*, a drug with good single-agent activity often used in adjuvant settings or metastatic disease, is not typically used in combination with radiation because of its tendency to sensitize even normal tissue to the toxic effects of ionizing radiation. The dose of radiation for patients treated concurrently is generally left up to the radiotherapist, but doses used in this setting are lower than those used for primary treatment of early-stage, medically unresectable patients. Most trials delivered radiation doses of about 60 Gy. With better techniques that can limit damage to normal tissues, radiation oncologists are seeking ways to escalate the dose of radiation to increase the rate of cure. PET scans have been used in a course of radiation to adjust the port to a shrinking tumor, permitting a greater dose to metabolically active tumor (and consequently less to healthy tissue), as defined by the PET scan. These ongoing studies are likely to impact on the future treatment of NSCLC.

Given that chemotherapy (typically two cycles) combined with radiation in stage III disease increases local control and

Table 67-1 Common Chemotherapy Regimens for Non-Small Cell (NSCLC) and Small Cell Lung Cancer

Drug	Most Common Toxicity	Comment
Stage III NSCLC		
Cisplatin *or* Carboplatin *Plus*	Nephrotoxicity Myelosuppression	Two cycles of combination chemotherapy are usually used concurrently with radiation. Patients with marginal performance status usually receive sequential therapy.
Paclitaxel *or*	Neuropathy, allergic reactions, myelosuppression	
Etoposide	Myelosuppression	
Stage IV NSCLC*		
Cisplatin *or* Carboplatin *Plus*	Nephrotoxicity Myelosuppression	Goal: give three or four cycles of two-drug combination. Can be combined with bevacizumab
Any of agents used for stage III disease *or*	Myelosuppression	
Gemcitabine *or*	Myelosuppression	Usually not used in combination with radiotherapy, due to potent radiosensitizing effects and greater incidence of normal tissue toxicity
Pemetrexed	Myelosuppression, mucositis, nausea	Approved only for non–squamous cell lung cancer
Small Cell Lung Cancer		
Cisplatin *or* Carboplatin *Plus*	Nephrotoxicity Myelosuppression	Goal: give four to six cycles of two-drug combination.
Etoposide *or*	Myelosuppression	
Irinotecan	Diarrhea, myelosuppression	
Second-Line Drugs		
Docetaxel	Hepatotoxicity, neutropenia, thrombocytopenia	Usually used as single agent in patients who relapsed after standard therapy
Gefitinib† *or* Erlotinib	Skin rash	Response is better in patients with tumors bearing activating-EGFR mutations.

*Patients with activating mutations in epidermal growth factor receptor (EGFR) have better survival when treated with first-line EGFR–tyrosine kinase inhibitors.
†Gefitinib is not approved in the United States.

reduces distant metastases, one might conclude that more chemotherapy must be better. However, available studies do not support the role of additional "consolidation" chemotherapy after concurrent chemoradiation. One trial randomized patients to either observation or three cycles of docetaxel after patients had completed standard cisplatin and etoposide (two cycles) with radiation. Subjects receiving docetaxel had more treatment-related toxicity, without improved survival, than the control group. Although trials addressing this question continue, for now there is no role for maintenance or consolidation chemotherapy, even for patients with an apparent complete response.

Another area that remains unsettled is whether there are patients with stage IIIA NSCLC who benefit from some combination of surgery with chemotherapy and radiation therapy. This question has engendered significant debate among experts, but RCTs comparing "definitive" chemoradiation therapy with induction chemoradiation followed by surgery show no differences in survival between the two groups. Does this mean that no patients can benefit from "trimodality" therapy, or that the proper subgroup best suited for this most aggressive approach has yet to be identified? All that can be said with certainty is that the use of neoadjuvant therapy followed by surgical resection cannot yet be considered the standard of care for unselected patients with stage IIIA NSCLC.

One readily identifiable but rare subgroup of patients with stage IIIA NSCLC that most experts would agree should receive surgery is those with T3 tumors (either by chest wall invasion or, in the new staging system, with tumors greater than 7 cm) and hilar nodal metastasis. This group of T3N1, stage IIIA patients are surgical candidates with or without neoadjuvant chemotherapy, as long as they have the physiologic reserve to tolerate complete resection. A consistent finding in trials of neoadjuvant chemotherapy followed by surgery is that patients demonstrating a "complete response" in the mediastinal nodes when restaged before surgery have the best prognosis. Whether this simply identifies a population of patients with a good prognosis (and therefore no need for surgery), or whether surgery itself contributes to favorable long-term survival in this group of patients, cannot currently be answered.

Superior Sulcus Tumors

Tumors in the superior sulcus, sometimes called *Pancoast tumors*, are most often stage IIB (T3N0) or IIIA (T3N1). As for other stage III NSCLCs, chemotherapy with concurrent radiotherapy is the preferred treatment for unresectable patients with acceptable performance status. When potentially resectable (as determined by an experienced thoracic surgeon), Pancoast tumors have been treated with preoperative radiation (30-50 Gy) followed by surgical resection. Studies examining multimodality treatment in patients specifically with superior sulcus tumors show that even with chest wall invasion or nodal involvement, patients with superior sulcus tumors treated with radiation, with or without chemotherapy, followed by surgery have an excellent chance at long-term survival, 30% to 40% at 5 years. In light of these favorable findings in nonrandomized studies, this approach has evolved to be the accepted standard of care.

Given the complexity of these patients, as well as the importance of timing surgery at an appropriate interval after thoracic radiation, patients with superior sulcus tumors offered potentially curative therapy are best served when treated by a multidisciplinary team of NSCLC specialists.

STAGE IV LUNG CANCER

Until the early 1990s, the utility of chemotherapy for metastatic lung cancer was a subject of debate, with a widely held belief being that systemic chemotherapy had no role for patients with stage IV NSCLC. That debate has ended. Studies have demonstrated convincing (but modest) survival benefit with chemotherapy. Metaanalyses show that two-drug chemotherapy regimens are better than single-agent treatment, but the addition of a third agent is associated with greater toxicity, without additional gain in survival. Response to modern combinations of chemotherapy, with more than 50% tumor shrinkage, occurs in 20% to 30% of patients with stage IV NSCLC. Complete clinical remission is rare (<5% of patients), and those who do respond to chemotherapy eventually relapse and die of their disease. Patients with excellent performance status clearly benefit from systemic chemotherapy, but many patients present with ECOG 2 performance status, representing a controversial population regarding the efficacy and risk of systemic chemotherapy for stage IV NSCLC. Subgroup analyses of clinical studies suggest that patients with performance status of 2 can benefit from active treatment, including systemic chemotherapy. Many oncologists treat such patients with a less intense dose schedule.

Despite advances in treatment of advanced NSCLC, therapeutic nihilism has remained prevalent among clinicians, generally more than in other types of solid-organ tumors. A metaanalysis of trials with patients randomly assigned to "best supportive care" versus chemotherapy, including a cisplatin-based regimen, showed a survival benefit in the chemotherapy group. The active chemotherapy group had a reduction in the risk of death of 27% and an absolute improvement in survival of 10% at 1 year. In the 1990s, many promising new chemotherapeutic agents (paclitaxel, docetaxel, irinotecan, vinorelbine, gemcitabine, pemetrexed), each with single-agent activity in advanced disease, were developed for and then used in patients who had stage IV NSCLC. Numerous trials evaluated combinations of one or more of these newer agents with a platinum compound (cisplatin or carboplatinum; see Table 67-1). No one combination of drugs is superior. However, with use of platinum-based combinations, median survival gradually increased to 8 to 9 months, with 1-year survival of 30% to 35%. This compares favorably with untreated patients with stage IV NSCLC, who have median survival of 3 to 4 months, with 1-year survival of approximately 15%. Although no data exist to define the optimum combination of chemotherapeutic agents, newer data are leading to increasingly individualized approaches to care.

Pemetrexed was compared with gemcitabine (both in combination with a platinum compound) in patients with metastatic cancer. The overall population showed no difference between the two drug combinations, but a prespecified subgroup of patients with non–squamous cell histology showed improved outcomes when treated with the platinum-pemetrexed combination. This has resulted in the first histology-based recommendation for systemic chemotherapy in NSCLC.

Erlotinib and *gefitinib*, oral inhibitors of the epidermal growth factor receptor (EGFR) tyrosine kinase, were initially studied and used as second-line or third-line agents for patients with relapsed or metastatic NSCLC. Responses were dramatic in some cases, and larger trials noted common epidemiologic traits in those with excellent responses to these drugs, including nonsmoking (or light smoking) history, female gender, adenocarcinoma histology, and Asian ethnicity. Further studies that sequenced the EGFR gene in tumors of responders and nonresponders found that the drugs were unusually effective in patients' tumors and cell lines bearing a few specific activating mutations affecting the tyrosine kinase domain of the EGFR gene. Further epidemiologic studies confirmed that activating mutations conferring sensitivity to EGFR-TKI drugs were also common in those who shared one or more of the demographic or histologic traits previously noted to confer a high likelihood of response: female, Asian, nonsmoking, or adenocarcinoma. A study in a mostly Asian population, for patients with tumors bearing activating mutations in EGFR, showed that first-line treatment with EGFR-TKI resulted in improved response and overall survival compared with standard chemotherapy among patients with mutant EGFR. In contrast, patients with tumors harboring wild-type EGFR fared better when treated with traditional cytotoxic chemotherapy.

Based on preclinical data demonstrating the importance of angiogenesis in supporting solid-tumor growth, targeted drug development for cancer has included anti-angiogenic agents, particularly drugs targeting vascular endothelial growth factor (VEGF) or its receptors. *Bevacizumab*, a fully human monoclonal antibody against VEGF, is the most advanced antiangiogenic agent in clinical use. In metastatic NSCLC, RCTs have demonstrated a modest but statistically significant survival benefit when bevacizumab was added to standard chemotherapy. In earlier Phase II trials, patients with large central tumors or with squamous cell histology had unacceptably high incidence of serious toxicity, specifically hemoptysis, and were specifically excluded from trials that resulted in the approval of bevacizumab for metastatic NSCLC. Bevacizumab use is also associated with a risk for hypertension and thrombotic complications and is contraindicated in patients with central nervous system (CNS) metastases.

An exciting addition in the field of targeted NSCLC therapy was the report in 2007 of a fusion protein, joining echinoderm microtubule–like 4 (*EML4*) with the anaplastic lymphoma kinase (ALK). EML4-ALK is an activating mutation capable of driving the proliferation of NSCLC cells. Drugs targeting abnormally activated ALK (e.g., crizotinib) were quickly developed and brought to clinical trials, showing great promise in patients bearing ALK mutations. Detecting ALK fusion can be difficult because it is typically formed by a short-segment chromosomal inversion. Fluorescent in situ hybridization (FISH) reagents developed for this purpose, called "break-apart FISH probes," can highlight this chromosomal rearrangement. Similar to mutant EFGR tumors, the prevalence of ALK-mutant NSCLC tumors in most series is small (~5%) and most often found in nonsmokers. Although this finding was relevant to only a small number of cancer patients, the exciting nature of this discovery is that within 2 years after the discovery of ALK's role in transformation of cancer cells, drugs targeting ALK were already in clinical trials, showing dramatic benefit for those with ALK-activating mutations. This pace of progression from discovery to treatment is highly unusual, not just in cancer, but in any field of biomedical research. Additional driving mutations similar to the one that activates ALK will likely be discovered in the future.

In summary, patients with metastatic, stage IV NSCLC and good performance status (ECOG 0-1) are best treated with systemic chemotherapy, with the addition of bevacizumab in those with no contraindication. Patients with ECOG performance status of 2 can also expect to benefit from active treatment, although with a higher risk of toxicity. Diagnoses in all patients should be made with biopsies that yield enough tissue to permit analysis for specific activating mutations in EGFR, or to detect the presence of an activating ALK fusion. Patients with these abnormalities, particularly EGFR mutations, are known (or suspected in the case of ALK) to gain prolonged survival when treated with agents targeted at their specific mutation.

SMALL CELL LUNG CANCER

The rationale for separately discussing SCLC is three-fold. First, the vast majority of patients with small cell lung cancer present with bulky mediastinal lymph node involvement or metastatic disease. Second, SCLC is much more likely to respond to systemic chemotherapy, and therefore patients with borderline performance status may still gain enough benefit from systemic chemotherapy to justify the known risk. Third, the major decision point for SCLC is the distinction between limited-stage and extensive-stage disease. Although small cell lung cancer is considered separately, it is important to recognize that the general principles of oncology for NSCLC still apply for SCLC. For example, the rare patient with SCLC who presents with an isolated pulmonary nodule or mass should be managed just as the patient with NSCLC, with appropriate preoperative staging followed by surgery for patients with acceptable pulmonary reserve. In such patients, postoperative adjuvant chemotherapy may improve long-term survival, but this has not been confirmed in RCTs, because the numbers are so small.

Although the updated (7th edition) staging system for lung cancer (see Chapter 66) has been validated in SCLC as well as NSCLC, the treatment of SCLC has traditionally focused on defining limited-stage versus extensive-stage SCLC. *Limited-stage SCLC*, the purview of the radiation oncologist, is defined by a tumor burden that can be encompassed within a single radiotherapy port with acceptable risk of toxicity. This applies to approximately 30% of patients with SCLC, in whom the addition of thoracic radiotherapy to systemic chemotherapy increases the likelihood of long-term survival. Approximately 20% of patients with limited-stage disease reach 5-year survival. For the remaining 70% of SCLC patients, with *extensive-stage disease*, the recommended treatment is systemic chemotherapy alone, and radiotherapy in these patients is limited to treating CNS metastases or symptomatic skeletal metastases.

As in NSCLC, no data from RCTs can provide the optimum chemotherapy regimen(s) in SCLC. Pooled data from meta-analyses suggest that patients treated with cisplatin-containing regimens have improved survival and acceptable toxicity. The agent most frequently used with cisplatin for SCLC is *etoposide*. RCT data also demonstrate the benefit of etoposide in SCLC, and etoposide in combination with cisplatin has been the standard of care in modern treatment of patients with SCLC. A few generally underpowered studies in SCLC patients have compared cisplatin with carboplatinum, which is generally better tolerated than cisplatin. Results are mixed; some data suggest a slightly better outcome with cisplatin, whereas another study shows equivalence. The number of cycles of chemotherapy varies between four and six. Additional chemotherapy beyond the sixth cycle increases the likelihood of toxicity without any appreciable increase in survival.

PROPHYLACTIC CRANIAL IRRADIATION

In patients treated for stage III or IV NSCLC or for SCLC, systemic chemotherapy is used to treat known or occult metastases. The CNS is a privileged site, and most chemotherapeutic agents are incapable of crossing the blood-brain barrier in sufficient amount to treat CNS metastases. Therefore, many studies address the role of prophylactic cranial irradiation (PCI) to reduce the development of symptomatic metastases. The rationale for this approach is strong, in that many lung cancer deaths result from CNS metastases, particularly with SCLC.

As expected, the strongest data favoring the use of PCI are from studies of patients with SCLC. The patients with the greatest demonstrable benefit are those with limited-stage SCLC in whom chemotherapy and thoracic radiation achieve a complete response. In these patients, PCI reduces the incidence of symptomatic CNS metastases and improves overall survival. PCI has been tested in patients with extensive-stage disease in SCLC as well. The cumulative risk of brain metastases within 1 year was 40.4% in the control group and 14.6% in the group receiving PCI. Median overall survival increased from 5.4 to 6.7 months, and 1-year survival of 27.1% versus 13.3% favored the patients receiving PCI. In NSCLC, the benefits of PCI are less than in SCLC, with one study of patients with mostly stage III NSCLC demonstrating a reduced incidence of symptomatic cranial metastases by more than 50% after PCI, but the difference in survival was statistically too small. This study was ended early because of slow data accrual, leaving the PCI survival benefit uncertain for patients with NSCLC.

PARANEOPLASTIC SYNDROMES AND OTHER COMMON COMPLICATIONS

Paraneoplastic syndromes are defined as systemic or localized effects of tumors unrelated to physical effects of the tumor mass. These syndromes can be divided into those caused by humoral factors produced by the tumor (hormones or other bioactive products) and those caused by immune response to the tumor in the form of autoantibodies. Most of the latter occur in the context of SCLC and result from a variety of antineuronal antibodies. Paraneoplastic syndromes can affect the skin, CNS and peripheral nervous system, vascular system, heart, kidneys, marrow, and muscular or skeletal system (Table 67-2).

One common paraneoplastic syndrome involves the inappropriate secretion of ADH by the tumor. The *syndrome of inappropriate antidiuretic hormone* (SIADH) disturbs fluid balance, results in the inability to dilute urine, and causes hyponatremia, which can progress to nausea, vomiting, muscle cramps, confusion, and convulsions. Treatment of SIADH begins with restricted water intake to prevent further hyponatremia (not completely correcting serum sodium level). Salt administration can be used to increase water excretion in the kidney. In extreme cases where sodium correction cannot be achieved using more conservative measures, demeclocycline can be used, and recently, vasopressin receptor antagonists have been tested for use in patients with SIADH.

Compression of the superior vena cava (SVC) and obstruction can occur from direct involvement of the SVC by centrally located tumors. Although this occurs infrequently in lung cancer, patients with lung cancer make up the majority of patients with *superior vena cava syndrome*, with the remainder having lymphoma or fibrotic lymphoid tissue (histoplasmosis or fibrosing mediastinitis). SVC syndrome was once considered a medical emergency, often prompting urgent radiation therapy to relieve the obstruction quickly. However, the principal concern of increased intracranial pressure (ICP) related to impaired venous outflow is rare, because SVC obstruction usually develops gradually and is often accompanied by the development of collateral venous circulation. Emergency treatment is no longer considered necessary for most patients. The importance of accurate histologic diagnosis before starting therapy cannot be overstated, given that the possibilities include

Table 67-2 Paraneoplastic Syndromes: Manifestations of Lung Cancer and Treatment

Syndrome	Manifestations	Treatment
Syndromes Caused by Production of Bioactive Hormones by Tumor		
SIADH	Hyponatremia	Water restriction Demeclocycline
Cushing's syndrome	Hypertension, glucose intolerance, electrolyte abnormalities, muscle weakness, weight loss, hirsutism, osteoporosis	Often improves with treatment of the cancer; can use ketoconazole, metyrapone, or mitotane
Hypercalcemia	Weakness, mental status changes, nausea	Treatment of the cancer Intravenous hydration Bisphosphonates, calcitonin
Syndromes Caused by Humoral Immune Responses to Tumor		
Lambert-Eaton myasthenic syndrome (LEMS)*	Weakness, muscle fatigue, often affects large muscle groups with preserved small muscle function; improvement with repetitive use	Usually improves with treatment of the cancer; can use plasma exchange or agents that increase synaptic depolarization (3,4-diaminopyridine) with or without pyridostigmine
Cerebellar degeneration†	Dizziness, nausea, vertigo, ataxia, and sometimes diplopia; onset can be abrupt	Symptoms often irreversible because of Purkinje cell loss
Limbic encephalitis‡	Cognitive impairment, mood changes, disordered perception, and sleep disturbances	Treatment may result in improvement; immune suppression may help if tumor is also treated.

*Antibody to voltage-gated calcium channel.
†Anti-Yo antibodies, or Purkinje cell antibody type 1 (PCA-1).
‡Anti-Hu antibodies or "antineuronal nuclear antibodies" (ANNA-1).
SIADH, syndrome of inappropriate (secretion of) antidiuretic hormone.

SCLC and NSCLC, as well as lymphoma. Placement of endovascular stents for severely symptomatic patients allows for rapid relief of SVC obstruction and time for proper staging and diagnosis. Important exceptions include patients who present with symptoms of increased ICP (headache, altered consciousness) or central airway obstruction threatening respiratory failure. These situations represent true medical emergencies, and these patients require endovascular stenting and/or emergent radiotherapy to decrease the risk of sudden respiratory failure and death. As always, securing the airway should be the first priority in these patients.

PALLIATIVE CARE

Despite advances in diagnosis, staging, treatment, and even screening, lung cancer will continue to be a major cause of morbidity and mortality. The majority of people diagnosed with lung cancer will die as a result of it, and clinicians must be prepared to manage and palliate acute or chronic, tumor-related symptoms at the end of life, when cancer-specific treatment is no longer indicated.

Principles of *pain management* for cancer patients include (1) recognizing and treating pain promptly; (2) involving the patient and family in pain control; (3) providing multimodal therapy; (4) reassessing and adjusting the management plan, focusing on intensity of pain, functional status, and side effects; and (5) documenting the plan and effectiveness of pain management. Pain control should include not only narcotics but also nonsteroidal antiinflammatory drugs (NSAIDs) and agents to alleviate neuropathic pain. Radiotherapy is an excellent means of rapidly controlling pain related to bony metastasis and should be used aggressively, particularly to reduce the risk of pathologic fracture.

Hemoptysis and large airways obstruction are common, frightening, and potentially life-threatening complications that can be palliated with a variety of approaches. Radiation therapy is a widely available tool to control hemoptysis and should be considered as a first option. Life-threatening hemoptysis can be managed by gaining rapid control of the airway (in patients for whom intubation is not contrary to agreed-on plans, prestated living will, or advance directives), followed by embolization of bronchial circulation. The latter should be attempted only by trained clinicians with significant experience in interventional vascular procedures. Lung, esophageal, or spinal cord infarction are potentially serious complications of bronchial arterial embolization.

Interventional bronchoscopic techniques can be useful for both hemoptysis, if the source of bleeding can be localized to a central airway, and malignant airway obstruction. Airway stents can be used in various ways to debulk the tumor. Balloon dilation, laser therapy, electrocautery, cryotherapy, and argon plasma coagulation can be used to achieve rapid palliation of severe dyspnea. Complex malignant airway obstruction should be managed only in centers with physicians trained and experienced in this procedure. Less rapid means of alleviating airway obstruction include external beam radiotherapy or, for patients who cannot receive EBRT, endobronchial brachytherapy.

Dyspnea occurs frequently in patients with advanced lung cancer, with varied causes. Dyspnea can result from underlying chronic obstructive pulmonary disease, extensive tumor burden, narrowing of a major airway, treatment-related toxicity, cardiovascular disease, or pleural effusion. Whenever possible, treatment of dyspnea should be directed at the underlying cause. When symptoms persist despite maximal treatment of potential contributing causes, however, opiates, oxygen, and bronchodilators can provide relief. Malignant pleural effusions are common and can cause dyspnea. Palliation can be achieved rapidly with therapeutic thoracentesis, but the presence of a pleural effusion does not guarantee that thoracentesis will improve dyspnea. Small to moderate-sized effusions are unlikely to be the root cause of dyspnea, and caution should be exercised before draining effusions ipsilateral to a known or suspected endobronchial obstruction. When a large volume thoracentesis results in lasting relief of dyspnea, placement of an indwelling tunneled pleural catheter can be considered, if the effusion recurs symptomatically.

Pericardial effusions, although less common than pleural effusions, can be life threatening if they produce increased intrapericardial pressure impairing cardiac return and ventricular filling. Pericardial effusions can develop acutely or more slowly, and the rapidity of development is proportional to the likelihood of symptoms. Treatment of the effusion should both relieve intrapericardial pressure from the fluid and prevent reaccumulation. Both goals can be accomplished in a single procedure if fluid drainage is accompanied by placement of an indwelling drain, pericardial window, or catheter-based balloon pericardiostomy.

Palliation and active treatment of cancer were once viewed as “mutually exclusive” approaches, but recent data suggest these may be complementary. In patients with metastatic lung cancer randomized to receive early palliative care or usual care (palliative care consultation only at request of patient, family, or oncologist) in combination with active oncologic treatment, early palliative care not only improved quality of life and lowered rates of depressive symptoms in the intervention group, but also resulted in longer median survival. Palliative care in these patients was delivered by a multidisciplinary team of physicians board-certified in palliative care and advanced-practice nurses. Personnel trained in palliative care should be an integral part of any multidisciplinary lung cancer patient care team. These intriguing findings, although not yet widely validated, suggest that attention to palliation can slow the dying process while providing superior quality of life.

CONCLUSION

Treatment of lung cancer is complex and requires accurate knowledge of both the anatomic stage of the tumor and the patient’s overall physiologic condition. Surgical treatment of lung cancer may be an option for patients once thought to be medically unresectable, and patients with borderline physiologic reserve should be seen by a multidisciplinary team. Postoperative adjuvant chemotherapy is now the standard of care for patients with stage II and III non–small cell lung cancer. Therapeutic nihilism for patients who are not candidates for curative surgery should be particularly discouraged; even patients with significant comorbidity can receive curative therapy that preserves quality of life while offering cure or prolonging survival. Patients and clinicians often have an unrealistically pessimistic outlook on the potential benefits of lung cancer treatment. Aggressive multimodality therapy for locally advanced, unresectable (stage III) NSCLC can still offer otherwise healthy patients a significant survival benefit, with 15% to 20% of patients achieving long-term survival. Therefore, patients with clinical stage III NSCLC should be offered realistic but hopeful assessment of their treatment options. Metastatic (stage IV) NSCLC is generally incurable, but also treatable.

Respiratory medicine physicians and other clinicians need to provide cancer patients with the best possible treatment, and in those with metastatic lung cancer and preserved performance status, this includes lung cancer–specific treatment, perhaps alongside early palliative care. Newer treatment options are becoming available at a rapid pace, and the role of novel, targeted therapies is being defined more precisely.

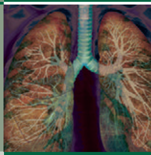
Section 12
LUNG TUMORS



Chapter 68
Benign Lung Tumors*

David E. Midthun

When used together, the words “tumor” and “lung” suggest “malignancy,” as expected given the frequency and lethality of lung cancer worldwide. The work of the respiratory medicine physician and the surgeon would be simpler if all focal opacities in the lung were malignant, but in reality, more are benign than malignant, requiring that the two be separated. A *tumor* is defined as abnormal benign or malignant growth, possessing no physiologic function, and arising from uncontrolled cellular proliferation. In a strict sense, “inflammation” is both physiologic and usually controlled, and thus does not fit this definition. However, in everyday practice, physicians know a focal opacity is present on imaging without knowing whether it is “physiologic” or “uncontrolled.” This chapter discusses the general approach to benign lung tumors and the most common benign neoplastic and non-neoplastic causes.

DETECTION AND DIAGNOSIS

We tend to use the terms *tumor* and *nodule* (or *mass*) synonymously. Benign tumors may also present primarily in the *airway* versus the lung parenchyma, and certain causes may present in either location or in both locations. Patients presenting with symptoms and found to have tumors on chest x-ray films or computed tomography (CT) imaging studies are more likely to have a lung malignancy.

Incidentally found tumors or nodules in the lung detected at CT screening are more likely to be benign. Studies of CT screening for lung cancer detect one or more nodules in about 25% of participants when CT collimation (slice thickness) is 10 mm and 40% to 60% of participants at 5 mm or less; about 98% of these nodules are benign. Nodule size is generally an excellent guide for determining benign from malignant; less than 1% of nodules 5 mm or less in diameter represent malignancy, even in current or former smokers. This distinction becomes more difficult for larger nodules, with the likelihood of malignancy more than 50% for nodules 2 cm in diameter, and increasing with larger nodule/mass size. A few benign tumors, such as hamartomas and teratomas, may have imaging features such that CT is diagnostic. However, most benign tumors do not have signature characteristics on imaging, and histology is required for diagnosis.

Positron emission tomography (PET) can be helpful in identifying benign from malignant tumors because it is based on the principle that cancer cells have a high rate of *glycolysis* compared with non-neoplastic cells. False-positive PET scans have been reported with infections, sarcoidosis, and other benign conditions. False-negative PET scans may occur with low-grade tumors, carcinoid tumor, and malignancies less than 1 cm in diameter. PET is now most often performed with integrated CT (PET-CT). Avidity on PET-CT is not the same as tissue, and a biopsy should be obtained rather than assuming a diagnosis or a stage.

Once a nodule is 3 cm or larger, and it is not clearly benign by showing evidence of calcification or fat on CT, the likelihood of malignancy is greater than 90%. Therefore, most benign tumors larger than 3 cm are diagnosed at resection because of the high index of suspicion of malignancy. Although most inflammatory lesions show no evidence of growth in follow-up, many benign tumors will grow and prompt concern for malignancy and subsequent removal for diagnosis. Bronchoscopy or transthoracic needle biopsy may be used to diagnose benign tumors, especially when multifocal or complete resection is not feasible.

Obstruction of the trachea and major bronchi is most often caused by squamous cell and small cell carcinoma or carcinoid tumor, but tracheal obstruction may also be caused by benign tumors. Several benign tumors manifest more frequently in the airways rather than the periphery of the lung. The patients may have symptoms of airway obstruction, such as cough, recurrent infection, wheezing, and dyspnea. The endoscopic appearance of a lesion may suggest a diagnosis, but uniformly, histology is required. If the lesion is polypoid and has a low likelihood of malignant behavior, successful treatment may be achieved with endoscopic techniques. Broad-based lesions and those with greater malignant potential are best treated with surgical excision; lung-sparing procedures such as a bronchoplasty or sleeve resection may be appropriate.

CLASSIFICATION

Benign neoplastic tumors are classified histologically according to the World Health Organization (WHO) classification updated in 2004 (Box 68-1). These histologic distinctions are more helpful to the pathologist than to the clinician approaching a lung tumor and are more likely to be in the “is it malignant or not” mindset. Although typically benign, many of the benign neoplasms have the potential for malignant transformation.

BENIGN EPITHELIAL NEOPLASMS

Papillomas

Benign epithelial neoplasms are generally rare, although *squamous papilloma* is the most common. Histologically, these are identified as papillary tumors with a squamous cell epithelial surface and delicate connective tissue attachments. They may be solitary or multiple and most often occur in the larynx and trachea, with less than 10% having lower airway involvement and only 2% within the lung parenchyma (Figure 68-1). The squamous type of papilloma has an association with human papillomavirus (HPV types 16, 18, 31, 33, and 35). Obstructive symptoms may develop from airway involvement and are an indication for laryngoscopic or bronchoscopic removal. Recurrent papillomas occur in as many as 20%, and some patients require periodic endoscopic debridement. Malignant transformation to squamous cell carcinoma may occur. Compared with squamous cell papillomas, glandular and mixed-cell papillomas are exceedingly rare.

Adenomas

Alveolar adenomas are rare and typically occur in the lung periphery. They are recognized as solitary tumors with a network of spaces lined by simple cuboidal epithelium and a spindle cell stroma. Although considered neoplasms, adenomas are not recognized as having malignant potential. *Papillary* adenomas also typically occur in the periphery of the lung and also appear to have no malignant potential. *Mucous gland* adenomas more often occur in the central airways and may be difficult to distinguish from low-grade mucoepidermoid carcinomas, although adenomas do not appear to be a malignant precursor. *Pleomorphic* adenomas have features of both epithelial and connective tissue differentiation; they occur in the airway or the lung periphery and may exhibit malignant behavior. *Mucinous cystadenomas* are localized cystic masses filled with mucin and lined by columnar mucinous epithelium; they are usually peripheral and are benign, without malignant progression.

*May exhibit malignant behavior.

Thymoma

Arising from ectopic thymic tissue, intrapulmonary thymomas are epithelial neoplasms and are otherwise identical to those occurring in the mediastinum. Myasthenia is rarely described with intrapulmonary thymoma, and more common symptoms include cough, fever, chest pain, and dyspnea. Resection is the treatment of choice, and invasion and nodal involvement may occur.

BENIGN MESENCHYMAL NEOPLASMS

Chondroma

Chondromas are benign tumors composed of cartilage and are most often found in the patient with *Carney triad:* pulmonary chondroma, gastric stromal sarcoma, and paraganglioma. Although described as a "triad," most patients will manifest only two different neoplasms. The appearance of chondromas on chest radiograph is usually diagnostic because these are typically multiple, well-circumscribed, calcified nodules occurring in young women (Figure 68-2). The main differential of the radiographic appearance of a chondroma is a hamartoma, typically singular. Chondromas are benign, and patients with Carney triad will more likely have symptoms from other, extrapulmonary manifestations.

Inflammatory Myofibroblastic Tumor

Synonyms for inflammatory myofibroblastic tumor (IMT) include inflammatory pseudotumor, plasma cell granuloma, fibrous histiocytoma, and fibroxanthoma. IMT is composed of a mixture of inflammatory cells (with plasma cell predominance), collagen, and spindle cells showing myofibroblastic

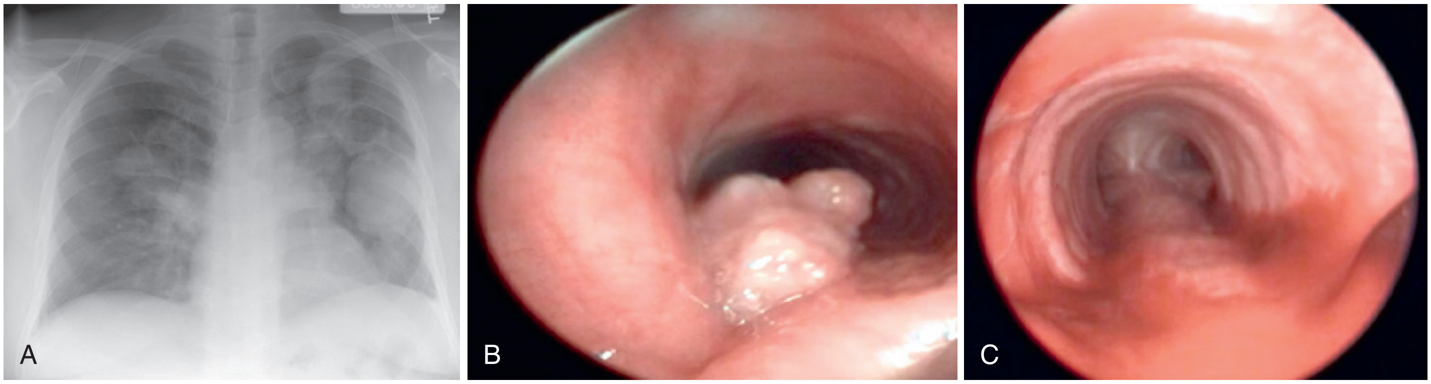

Figure 68-1 **A,** Chest radiograph in 56-year-old man with history of respiratory papillomatosis diagnosed by wedge resection of one of several masses. At bronchoscopy, obstructing papillomas were seen in the trachea (**B**) and distal bronchial tree and were removed with rigid bronchoscopy (**C**).

differentiation. IMTs are the most common benign primary lung tumor in children and usually occur in the airways. In adults these lesions are rare and more often present as solitary parenchymal masses (Figure 68-3). Symptoms may include weight loss and fatigue or pain relating to tumor location; chest wall invasion or angioinvasion can occur. Resection is the only proven treatment, and complete excision is usually curative, although recurrence after excision and metastases or progression to sarcoma can occur.

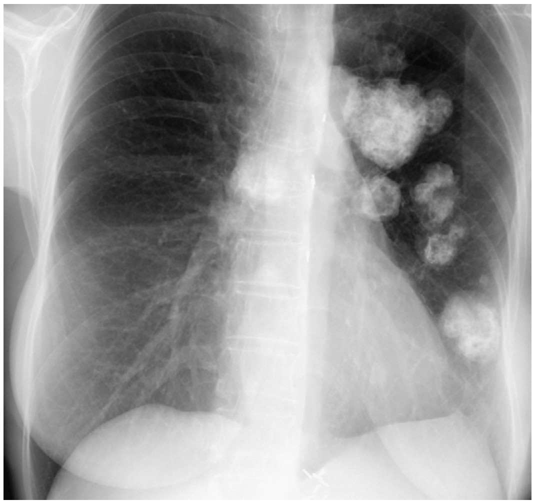

Figure 68-2 Chest radiograph in 25-year-old woman shows multiple calcified pulmonary chondromas. Patient had prior resection of several gastrointestinal stromal tumors (GISTs) and was believed to have Carney triad; she had not demonstrated a paraganglioma.

Neurofibromas

The neurofibromatoses (NFs) are autosomal dominant disorders and may be associated with benign peripheral *nerve sheath tumors* in the airway or lung (Figure 68-4). A retrospective study of 156 patients with NF found lung nodules or masses present in 5%, not including those with paraspinal or chest wall masses. Neurofibromas and *schwannomas* may also be present in the absence of NF, and there is the potential for malignant change. Clinical signs and symptoms typically relate to airway obstruction (cough, wheezing, dyspnea, hemoptysis).

Solitary Fibrous Tumor of Pleura

Solitary fibrous tumors of the pleura (SFTPs) are spindle cell mesenchymal tumors. They typically arise in the visceral pleura, but also from lung parenchyma or mediastinum, and may become very large (Figure 68-5). The terminology of "benign mesothelioma" is no longer used. In one retrospective series of 84 patients, 55% were symptomatic (cough, chest pain, dyspnea); 4% had the paraneoplastic manifestations of hypertrophic pulmonary osteoarthropathy (HPO), 6% had HPO and clubbing, and 1% hypoglycemia. Rarely, SFTP can be malignant.

Glomus Tumor

Glomus tumors are extremely rare, occur more often in males, and are thought to be of glomus cellular origin, having the

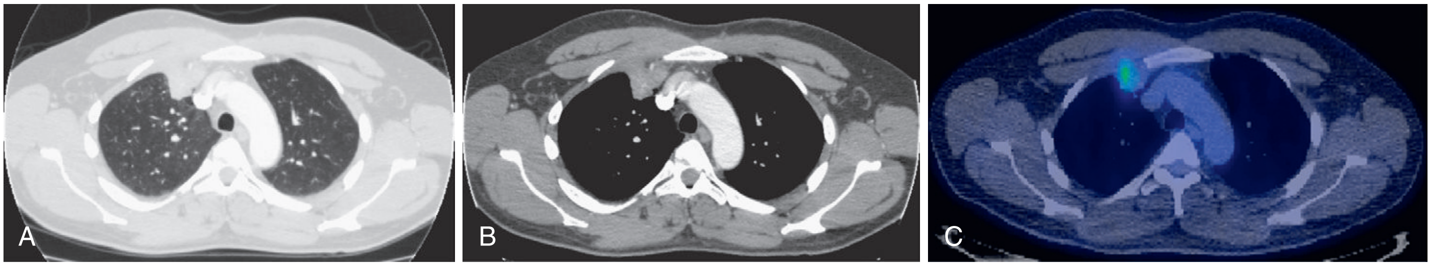

Figure 68-3 Computed tomography (CT) scans in 40-year-old man, never smoker who developed pain in right side of chest, show a mass anteriorly in **A,** right upper lobe of lung, and **B,** mediastinal windows. **C,** Positron emission tomography (PET)–CT shows lesion with moderate activity. Transthoracic needle biopsy was nondiagnostic. Surgical biopsy showed inflammatory myofibroblastic tumor, and patient underwent complete resection.

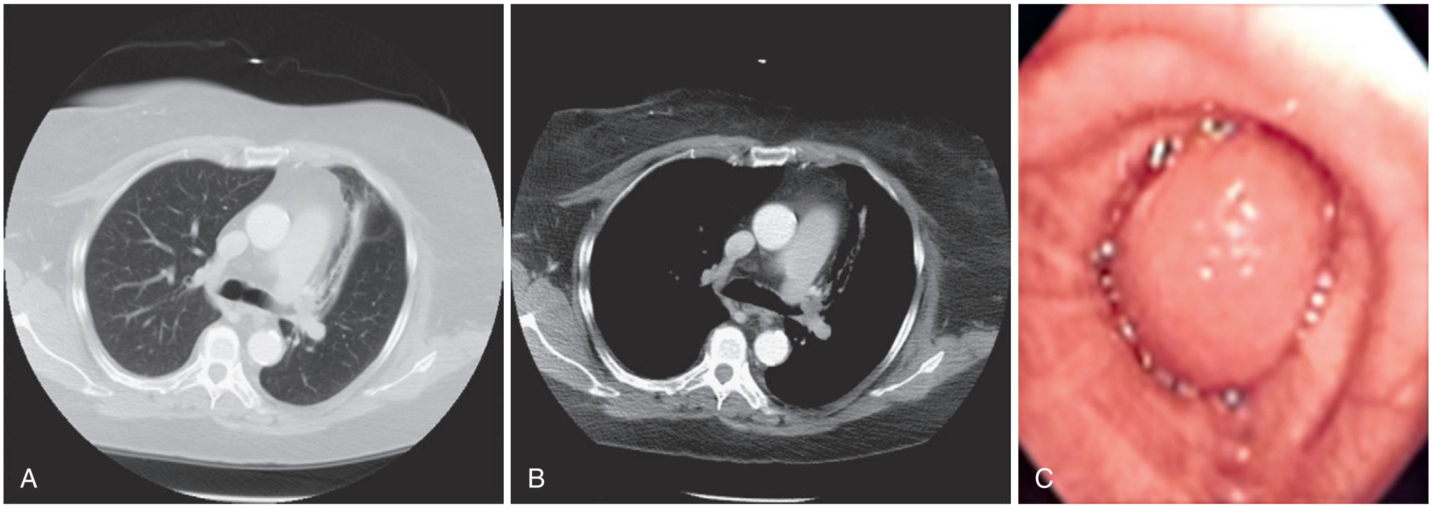

Figure 68-4 **A,** Chest radiograph in 68-year-old woman with history of asthma presenting with worsening cough and dyspnea shows volume loss. **B,** CT scan shows obstruction of left main bronchus. **C,** Bronchoscopy reveals complete obstruction of left main stem by a polypoid tumor. Patient underwent left thoracotomy, with resection of a sleeve of bronchus at takeoff of left upper lobe of lung; pathology revealed a neurofibroma.

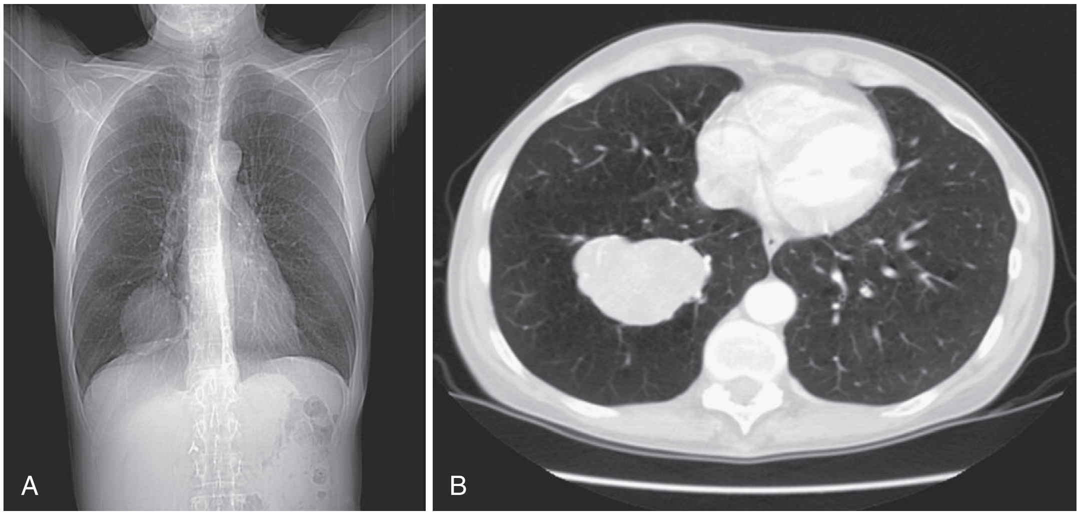

Figure 68-5 **A,** Chest radiograph identifies a mass in an asymptomatic 61-year-old woman, former smoker. **B,** CT scan shows mass without adenopathy, and lobectomy showed this to be a 7-cm solitary fibrous tumor with no involvement of the pleura.

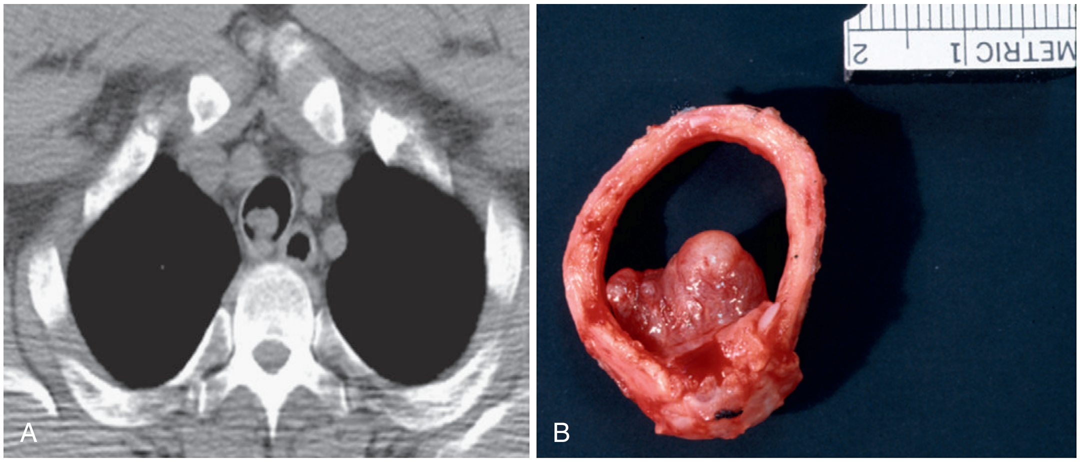

Figure 68-6 **A,** CT chest scan shows a tracheal lesion in 41-year-old man, never smoker, who presented with intermittent hemoptysis for 2 years; chest radiograph was normal. Bronchoscopy showed a broad-based polypoid lesion, and patient underwent tracheal sleeve resection. **B,** Pathology showed glomus tumor.

appearance of smooth muscle. Based on cellular appearance, they are further classified as *classic* glomus tumor, *glomangioma*, and *glomangiomyoma*. Within the chest, glomus tumors are more likely to be in the trachea, but they have been described in the lung and mediastinum (Figure 68-6). Successful resection has been reported with surgery or bronchoscopy, and malignant behavior has been observed.

BENIGN NEOPLASMS: MISCELLANEOUS

Hamartoma

Pulmonary hamartomas are the most common benign neoplasms in the lung, comprising cartilage, fat, connective tissue, and smooth muscle. Hamartomas are rare in children; in adults they are usually in the parenchyma, and approximately 10% present endobronchially (Figure 68-7). Patients with *parenchymal hamartoma* are usually asymptomatic, and typical features of fat and calcification may be evident on CT images. When lacking classic CT features, parenchymal hamartomas are often diagnosed at resection to exclude malignancy. Rarely, recurrence or sarcomatous transformation has been described.

Sclerosing Hemangioma

Histologic features of sclerosing hemangiomas include papillary, solid, sclerotic, and hemorrhagic structures. Sclerosing hemangiomas usually present as asymptomatic radiographic abnormalities, although cough, hemoptysis, and pain may occur. Sclerosing hemangioma behaves benignly. Although spread to regional lymph nodes is described rarely, when present, it appears to have no negative effect on prognosis, and disease-related death has not been reported.

Benign Teratoma

Teratomas are composed of tissues from more than one germ cell line and have mature and immature forms. Mature pulmonary teratomas are benign and more common in the upper lobes of the lung. Immature teratomas may be malignant. Because teratomas are frequently cystic and contain skin, hair, sweat glands, fat, bone, sebaceous material, or toothlike structures, some of these elements may be visible on CT scans. Patients with teratomas may be asymptomatic or may present with chest pain, hemoptysis, or the unusual symptom of *trichoptysis*, expectorating hair. Surgery is generally recommended, even if the diagnosis is evident from imaging studies (Figure 68-8).

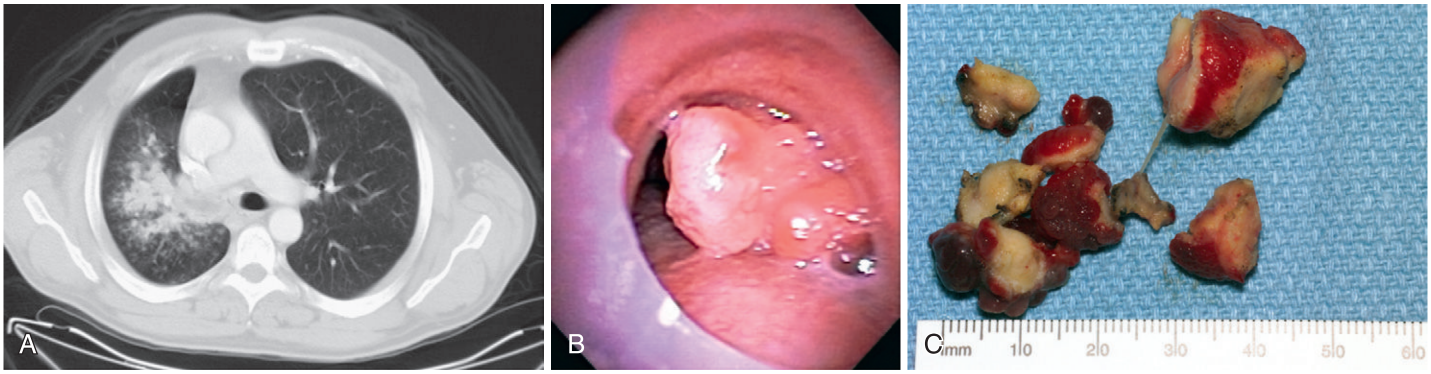

Figure 68-7 **A,** CT chest scan shows complete obstruction of right main bronchus and postobstructive pneumonia in 45-year-old man who presented with fever, sweats, and chills; chest radiograph showed right lung opacity and volume loss. **B,** Bronchoscopy demonstrates a polypoid mass extending into distal trachea. **C,** Bronchoscopic resection was performed using polypectomy snare, and pathology showed hamartoma.

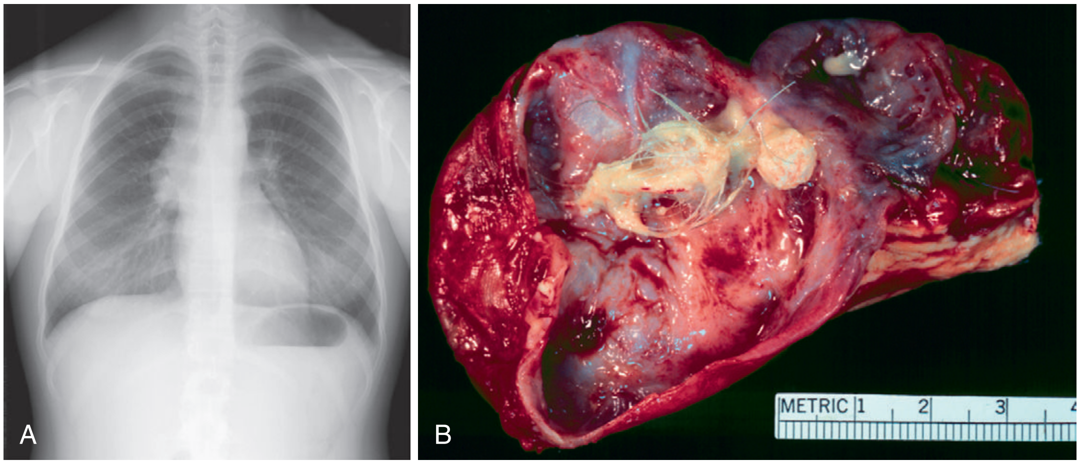

Figure 68-8 **A,** Chest radiograph shows a right hilar mass in 17-year-old girl who had chest discomfort after a basketball game. **B,** Resection shows benign, cystic teratoma.

Clear Cell Tumor

The name "clear cell" tumor comes from presence of cells with abundant clear or eosinophilic cytoplasm containing glycogen; it is also called "sugar tumor." This extremely rare tumor is usually solitary and peripheral, and discovery is incidental. Rarely, malignant features have been described.

Leiomyoma

Leiomyomas are benign smooth muscle tumors occurring in women. When singular, and absent a history of uterine leiomyomas, they most often occur in the airway. Benign leiomyoma may also present in the lung of women with a history of uterine leiomyoma and is termed *benign metastasizing leiomyoma* (BML). BML is characterized by multiple, slow-growing, smooth muscle tumors (Figure 68-9). Despite the resemblance to malignancy, the number of mitotic indices is low, and there is no evidence of invasion despite multiple distant lesions. Extrauterine leiomyosarcoma must be excluded. The lung involvement in BML is typically evident 10 to 15 years after the removal of the uterine leiomyoma. BML is usually negative on PET imaging. Treatment includes hormonal therapy, surgical resection, and chemotherapy.

Lipoma

Lipomas are rare, are composed of mature fat cells, and may occur in the airway or less often in the mediastinum. Presenting symptoms depend on the size and location of the lesion, most often dyspnea and cough. CT imaging shows the lesion to be homogeneous and composed of fat (Figure 68-10). Local recurrence has been described after resection.

NON-NEOPLASTIC TUMORS

A variety of conditions cause benign lesions in the lung that are not true neoplasms (Box 68-2). These conditions need to be considered in the differential diagnosis when evaluating a nodule or mass on imaging studies and include nodular lymphoid hyperplasia, organizing pneumonia, endometriosis, rounded atelectasis, and sequestration, as discussed in earlier chapters.

Amyloid Deposits

As an example of a non-neoplastic tumor, amyloid is composed of a group of fibrillar proteins with beta-pleated-sheet formation, which demonstrates birefringence under polarized light

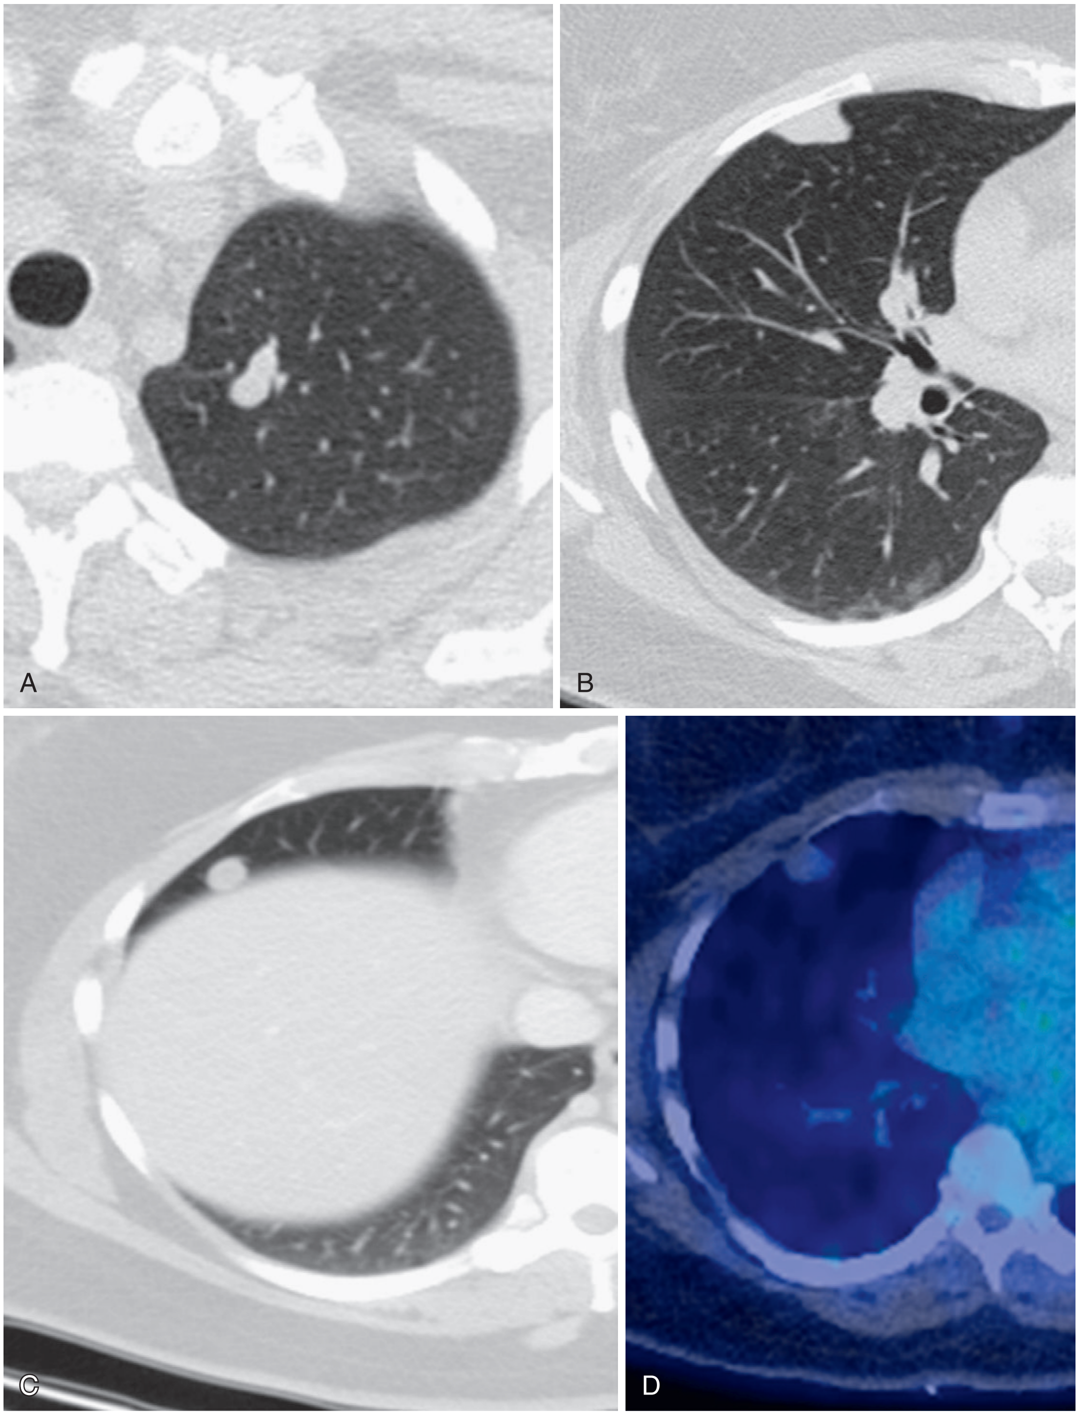

Figure 68-9 A 37-year-old former smoker had an abdominal CT done for pain and a lung nodule was seen. CT chest scans **A, B,** and **C** showed multiple lung nodules. **D,** PET-CT scan shows no activity. Patient had no history of malignancy but had a hysterectomy 7 years earlier for fibroid tumors. Needle biopsies of a nodule showed spindle cell neoplasm, consistent with benign metastasizing leiomyoma.

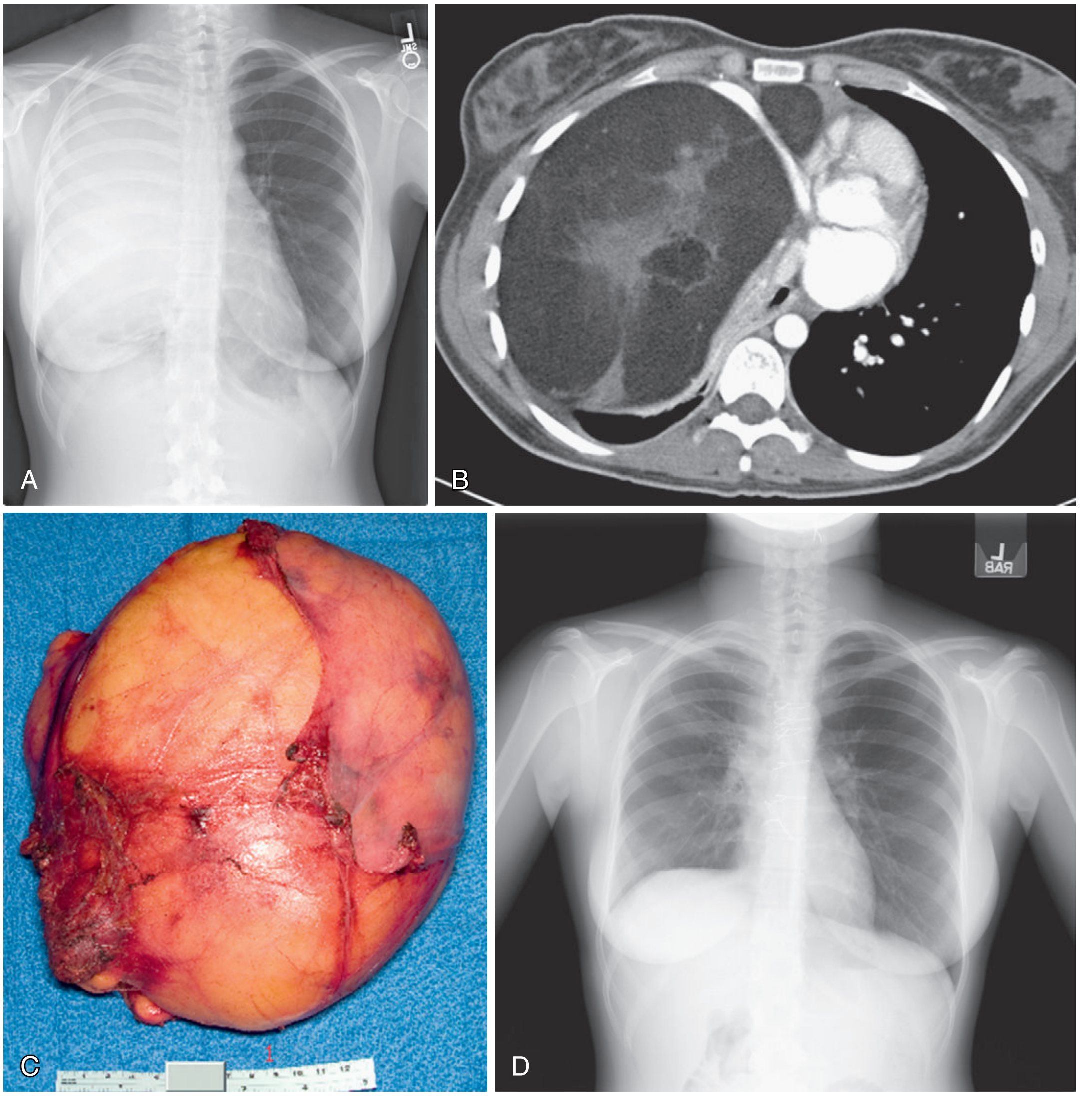

Figure 68-10 **A,** Chest radiograph reveals opacification of right side of chest in 24-year-old woman presenting with cough for 6 weeks and mild exertional dyspnea. **B,** CT scan shows a large, fat-attenuating mass. **C,** Thoracotomy reveals well-circumscribed benign lipoma (23.0 × 11 cm) with no clonal abnormality. **D,** Radiograph at 8 weeks postoperatively shows reexpansion of right lung.

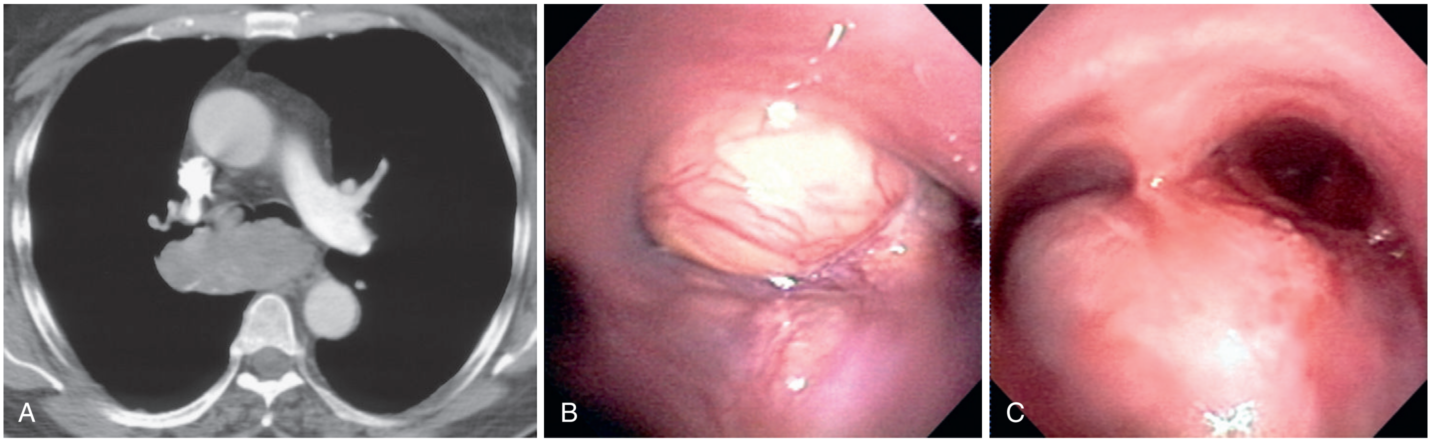

Figure 68-11 **A,** CT scan shows mass obstructing right main stem bronchus in 61-year-old man, never smoker, with 12-year history of asthma, presenting with progressing shortness of breath; chest radiograph showed volume loss in right lung. **B,** Bronchoscopic biopsies show amyloidoma. **C,** Rigid bronchoscopic resection reestablished patency of right main bronchus.

Section 13
DISORDERS OF THE PLEURA AND MEDIASTINUM

Chapter 69

Pleural Effusion, Empyema, and Pneumothorax

John M. Wrightson • Helen E. Davies • Y.C. Gary Lee

PLEURAL EFFUSION

Pleural effusion, defined as the accumulation of fluid in the pleural space, is common and affects more than 3000 people per 1 million population each year. Pleural effusions develop when the rate of pleural fluid formation exceeds that of absorption and may be a complication of pleural, pulmonary, and systemic disease or associated with use of certain drugs. A systematic approach is required to determine the underlying cause.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

EPIDEMIOLOGY

More than 60 causes of pleural effusions have been documented. The relative incidence of different types of effusion varies according to patient demographics and geographic areas. Heart failure is responsible for approximately one third of all pleural effusions (Table 69-1), with pleural infection and malignancy accounting for most exudative effusions.

PATHOPHYSIOLOGY

In the healthy person, the pleural cavity contains a small amount of physiologic pleural fluid (less than 10 mL in a 70-kg man), which functions in part to facilitate smooth gliding of the lung over the interior chest wall during respiration. The normal rate of fluid production is approximately 17 mL/day. The fluid is resorbed into lymphatic channels, with an estimated maximal absorptive capacity of 0.2 to 0.3 mL/kg/hour.

With *transudative* effusions, pleural fluid accumulates because of an increase in hydrostatic pressure or a reduction in plasma oncotic pressure; the pleura usually remain normal. By contrast, development of *exudative* effusions normally is the result of various pleural pathologic conditions, resulting in increased vascular permeability and/or impaired fluid resorption (e.g., lymphatic obstruction).

Pleural fluid also can accumulate from extrapleural sources. Transdiaphragmatic migration of peritoneal fluid is well recognized. Abnormal communications between the pleural cavity and the thoracic duct (chylothorax), esophagus, pancreas, renal tract (urinothorax), or dura mater also may lead to development of pleural effusions.

CLINICAL PRESENTATION

Patients may be asymptomatic but often present with dyspnea, chest pain, cough, or other signs or symptoms of underlying disease. Dyspnea is a result of altered diaphragmatic and chest wall mechanics and compression of the lung. Pleuritic chest pain indicates disease involvement of the parietal pleura. Physical examination reveals a stony dull percussion note with decreased fremitus and absence of breath sounds over the effusion. These signs may be difficult to distinguish from those of an elevated hemidiaphragm.

IMAGING

Chest Radiography

Most pleural effusions can be recognized on posteroanterior (greater than 200 mL fluid volume) or lateral (greater than 50 mL fluid volume) chest radiographs. Large effusions may produce contralateral mediastinal shift. Blunting of the costophrenic angle may be the only sign for a small effusion but may also represent pleural thickening.

Thoracic Ultrasound Imaging

The availability of bedside thoracic ultrasound examination by clinicians has had a significant impact on pleural disease management in recent years. The 2010 British Thoracic Society Pleural Disease Guidelines strongly recommended the use of thoracic ultrasound imaging before procedures for pleural fluid. It is particularly useful for the detection (sensitivity approximately 100%), quantification (by depth), and characterization of pleural fluid (Figures 69-1 to 69-3; Table 69-2), as well as for guiding intervention. Ultrasonography is invaluable in the differentiation between pleural fluid and collapsed or consolidated lung, thereby avoiding unnecessary pleural procedures and associated complications.

Thoracentesis guided by clinical examination alone could result in organ puncture in 10% of cases. Several large studies have demonstrated improved safety of pleural interventions performed under ultrasound guidance, particularly in reducing iatrogenic pneumothorax or organ puncture. A Mayo Clinic study showed a dramatic reduction (from 8% to 1%) in rate of thoracentesis-related complications since the unit initiated a "pleural safety program" that included pleural ultrasound training and mandated its use before thoracentesis. With adequate

Table 69-1 Approximate Annual Incidence of Various Types of Pleural Effusions in the United States

Causative Disorder	Number	Percentage	Percentage of Noncardiac Effusions
Congestive heart failure	500,000	37.4	
Other causes		62.6	
Pneumonia	400,000		48.0
Malignant disease	200,000		24.0

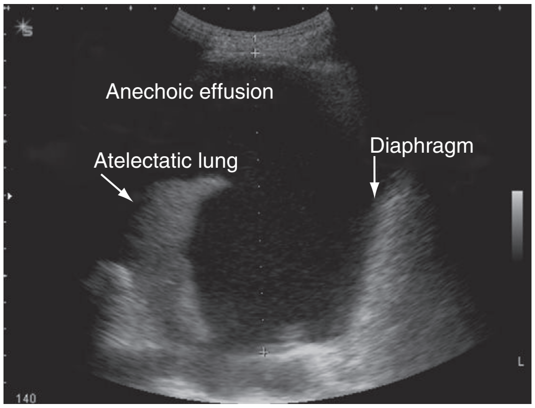

Figure 69-1 Thoracic ultrasound image demonstrating a large anechoic effusion with compressive atelectasis of underlying lung.

Table 69-2 Pleural Fluid Sonographic Appearances

Sonographic Appearance	Significance
Anechoic (black fluid) (see Figure 69-1)	Transudative or exudative effusion
Septated (multiple lines within fluid) (see Figure 69-2)	Exudative effusion; may suggest possible difficulties inserting chest tube; effusion may drain poorly, although not necessarily
Echogenic (echoes, often swirling, within fluid) (see Figure 69-3)	Exudative effusion; heavily echogenic fluid suggestive of blood or pus

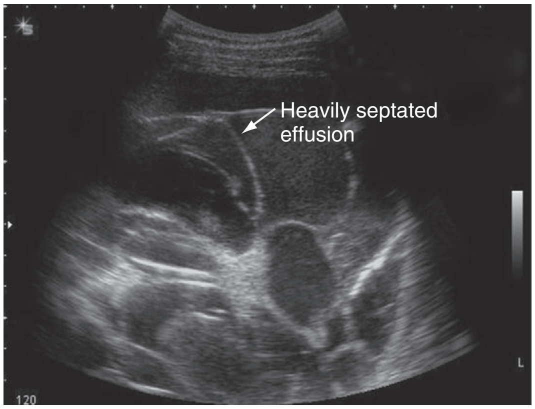

Figure 69-2 A heavily septated effusion is evident on this ultrasound image.

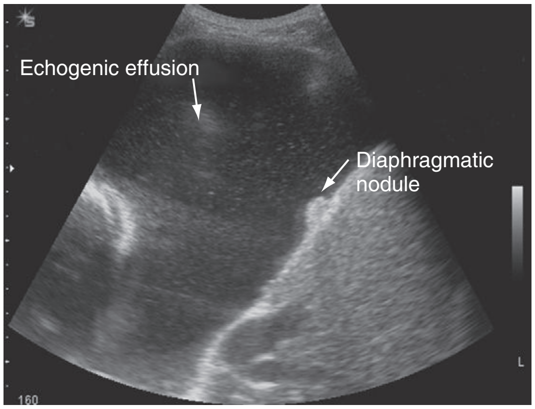

Figure 69-3 Ultrasound appearance strongly suggestive of malignancy, with diaphragmatic nodularity and a large echogenic exudative pleural effusion.

training in this modality, thoracic ultrasound imaging performed by respiratory physicians has been shown to have a safety profile comparable to that when performed by radiologists.

Ultrasound imaging has a high sensitivity (approximately 80%) for detecting pleural malignancy, which can manifest as thickening or nodularity on the visceral, parietal, and diaphragmatic pleural surfaces (see Figure 69-3). Detection of pleural nodularity mandates further investigation (e.g., with chest computed tomography [CT] and pleural biopsy), even if there are no further suspicious features. Ultrasonography also can identify abnormalities beyond the pleural cavity that may provide vital clues to the cause of the effusion, including peripheral lung tumors or abscesses, parenchymal consolidation and atelectasis, diaphragmatic paralysis or elevation, pericardial effusion, and rib and liver metastases and enables evaluation of supraclavicular and cervical lymphadenopathy (**Figure 69-4**).

Pleural interventions may be guided by site marking or real-time needle visualization; the latter is required to sample small or loculated effusions. The Royal College of Radiologists (in the United Kingdom), the American College of Chest Physicians, the American College of Surgeons, and the American College of Emergency Physicians are among the many agencies that have published ultrasound training guidelines for clinicians. Appropriate training is essential, because potential pitfalls with performance and interpretation of pleural ultrasound studies are recognized.

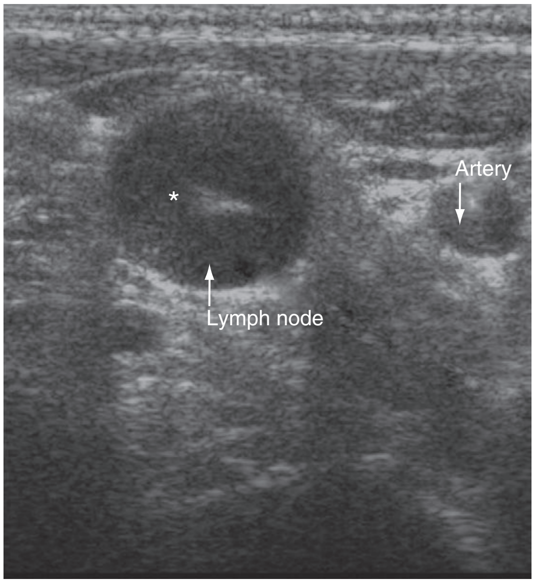

Figure 69-4 Neck ultrasound image showing an enlarged, rounded, hypoechoic lymph node characteristic of malignancy, undergoing fine needle aspiration with a 21-gauge needle (*indicates needle tip).

Computed Tomography and Magnetic Resonance Imaging

CT with pleural phase contrast enhancement highlights pleural abnormalities and aids discrimination of benign from malignant disease (see Chapter 7). Specific "pleural" CT protocols should be adopted for optimal pleural enhancement and abnormality detection; recent data suggest that images should be acquired 60 seconds after injection of 150 mL of an intravenous contrast agent at 2.5 mL/second. The presence of contraction of the hemithorax, mediastinal pleural involvement, and circumferential pleural thickening (especially greater than 1 cm and with nodularity) all are suggestive of pleural malignancy (**Figure 69-5**) but cannot adequately differentiate mesothelioma from metastatic pleural cancers. Magnetic resonance imaging (MRI) can help delineate malignant chest wall involvement and is valuable in selected cases, particularly when (probably benign) pleural abnormalities are to be followed clinically by serial imaging in younger patients.

Positron Emission Tomography

Positron emission tomography (PET)-CT scanning (see Chapter 8) is beginning to emerge as a useful tool in pleural disease management. PET-CT cannot adequately differentiate between benign and malignant effusions, because of the tracer ^{18}F-fluorodeoxyglucose (FDG). FDG-enhanced PET imaging is confounded by avid pleural uptake of FDG in the presence of pleural inflammation (including that due to previous talc pleurodesis and pleural infection). However, FDG-PET may have a role in guiding pleural biopsy in patients with diffuse pleural abnormality to increase sensitivity (**Figure 69-6**). FDG-PET also may identify nonpleural sites that allow tissue sampling to confirm malignancy (e.g., lymphadenopathy or liver metastases). Recent data suggest a role for FDG-PET in monitoring disease response to therapy in malignant mesothelioma, as well as a potential prognostic role.

PET scanning using various novel molecular tracers is in early-phase trials for evaluation of pleural malignancies. For instance, PET scanning using labeled thymidine, essential for deoxyribonucleic acid (DNA) synthesis, can identify sites of cell proliferation activity and is not confounded by inflammation (**Figure 69-7**). New tracers targeting specific cell biology processes (e.g., annexin, a marker of apoptosis) are likely to provide valuable insight to disease pathobiology.

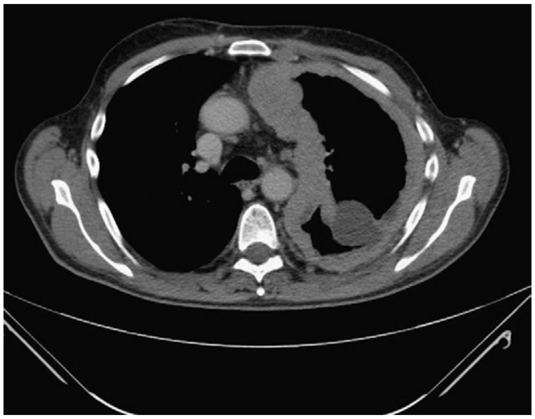

Figure 69-5 Thoracic computed tomography (CT) scan showing circumferential nodular pleural thickening and hemithorax volume loss due to malignant pleural disease.

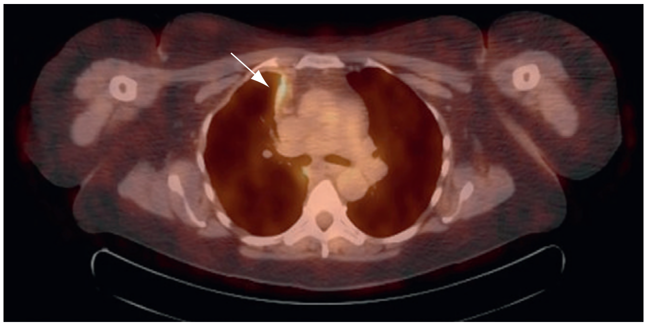

Figure 69-6 Positron emission tomography–computed tomography (PET-CT) image demonstrating localized fluorodeoxyglucose (FDG)-avid mediastinal pleural thickening (*arrow*) in mesothelioma.

DIAGNOSTIC APPROACH

Investigation of a pleural effusion should be performed using a systematic approach (**Figure 69-8**), aiming to minimize the number of pleural procedures required to make a diagnosis and thereafter allow definitive treatment.

Thoracentesis, preferably imaging-guided, should be the initial investigation in pleural effusions of uncertain origin. If small (less than 1 cm in depth) effusions require sampling, this procedure should be undertaken using real-time radiologic guidance. Thoracentesis is generally safe and complications are uncommon but include vasovagal syncope (0.6%), pneumothorax, infection, and bleeding. Removal of large amounts of fluid may precipitate reexpansion pulmonary edema, often heralded by cough, chest discomfort (at which point the procedure must be terminated), or acute dyspnea. Pleural manometry has been advocated but is not widely available. If initial pleural fluid analysis is inconclusive, additional investigations are often required, including further imaging, repeat thoracentesis, and thoracoscopic or percutaneous pleural biopsy (see Chapters 13 and 74).

PLEURAL FLUID ANALYSIS

Pleural fluid analysis can help determine the diagnosis or direct further investigations. Recent years have seen a significant

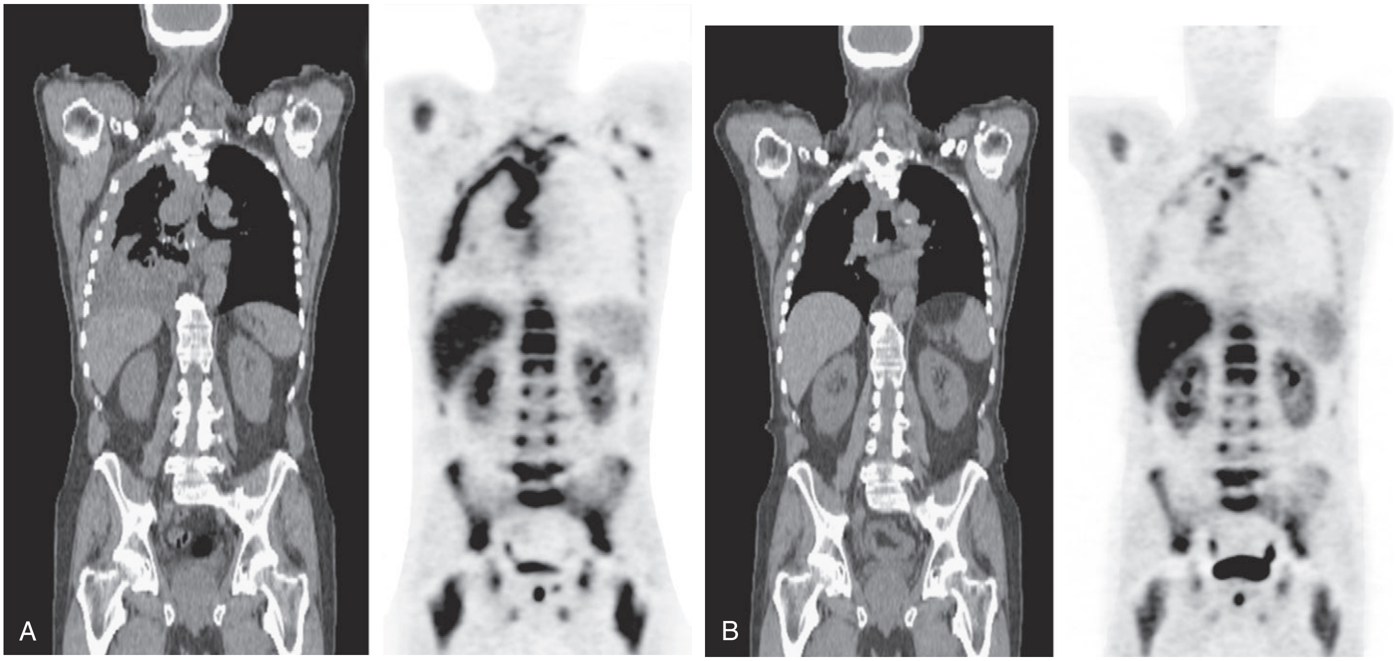

Figure 69-7 Positron emission tomography (PET) imaging using labeled thymidine in a patient with mesothelioma. Images before (**A**) and after (**B**) chemotherapy reveal dramatic improvement in the costal and mediastinal pleural uptake with treatment. *(Courtesy Dr. Roslyn Francis, University of Western Australia, Australia.)*

(Investigations requested should correlate with suggestive or actual clinical findings.) *AAFB*, acid- and alchohol-fast bacilli; *LDH*, lactate dehydrogenase; *MCS*, microscopy, culture, and sensitivity [testing]; *PE*, pulmonary embolism; *TB*, tuberculosis.

Box 69-1 Light's Criteria

A pleural fluid is an *exudate* if any of the following criteria are met:

1. Pleural fluid–to–serum protein ratio greater than 0.5
2. Pleural fluid–to–serum lactate dehydrogenase (LDH) ratio greater than 0.6
3. Pleural fluid LDH more than two-thirds the upper limit of normal serum LDH

Caveat: False-positive results may occur in patients with cardiac failure on diuretic therapy resulting in a pleural fluid–to–serum protein ratio greater than 0.5. Clinical judgment and measurement of N-terminal pro-BNP will define a true transudate in these circumstances.

increase in the tests and biomarkers available for pleural fluid analysis, but the exact role(s) of many of them in the diagnostic algorithm are still to be defined. An understanding of the indications and limitations of the individual tests is essential for clinicians to provide an efficient and cost-effective service.

Bedside Examination of the Fluid

Most pleural fluids are straw-colored (serous), serosanguineous (blood-stained), or hemorrhagic. A genuine hemothorax is characterized by fluid hematocrit greater than 50% of blood hematocrit.

Appearance of the fluid may reveal the diagnosis: presence of pus confirms empyema; food particles in the fluid suggest esophageal perforation; and chylous fluids suggest chylothorax or pseudochylothorax. Pleural fluid that appears milky should be centrifuged: in empyema, a clear supernatant is seen, whereas chyle remains cloudy. The odor of ammonia often is the most important diagnostic clue to the presence of urinothorax.

Separation of Exudates and Transudates

Exudative pleural effusions most commonly are defined by *Light's criteria* (Box 69-1), using the fluid-to-serum ratio of

Box 69-2 Common Causes of Pleural Effusion for Categories of Pleural Fluid Differential Cell Count

Lymphocytic Effusion (>85% total nucleated cells)

Parapneumonic
Pulmonary embolism

protein and lactate dehydrogenase, which has an accuracy of 96%. Numerous other markers and criteria have been tested (including measurement of pleural fluid cholesterol values), but none has proved superior. Distinguishing exudates from transudates may narrow the scope of the differential diagnosis and streamline further investigations, although such categorization has limitations: It does not provide the diagnosis and fails to identify concurrent transudative and exudative causes of fluid formation. Research in recent years has focused on disease-specific markers that may provide a definitive diagnosis.

Differential Leukocyte Count

The cellular portion of physiologic pleural fluid consists predominantly of macrophages and monocytes. In disease states, the differential cell count of the pleural fluid may be helpful in determining the cause (Box 69-2). Acute pleural inflammation or injury generates chemotaxins, such as interleukin 8, and attracts neutrophils to the pleural space. A neutrophil-predominant effusion is commonly seen with acute bacterial pneumonia or pulmonary infarction. A lymphocyte-rich fluid is more common in disease of insidious onset such as tuberculosis (TB) or malignancy. Tuberculous effusions occasionally (less than 10%) may be neutrophilic. An increased eosinophil count (more than 10% of total leukocytes) is often nonspecific. Most commonly, eosinophil effusions develop secondary to presence of intrapleural air or blood (including pneumothorax or previous interventions) but can also be associated with a range of other diseases, such as Churg-Strauss syndrome or drug-induced pleuritis.

pH and Glucose

Pleural fluid pH (or glucose) measurement can aid disease management. Low glucose levels are associated with a similar spectrum of diseases that give rise to low pH effusions (e.g., infection and connective tissue diseases) (Box 69-3) and are equally informative except in patients with hyperglycemia.

Physiologic pleural fluid pH is approximately 7.6 and reflects bicarbonate accumulation within the pleural cavity. Pleural fluid pH should be measured using a blood gas analyzer, and care should be taken to avoid exposure of the fluid to free air or to residual lidocaine, which will potentially raise or lower the fluid pH, respectively. pH meters and litmus paper have been shown to give unreliable values. Low pleural fluid pH (e.g., less than 7.3) coexistent with a normal blood pH may result from increased metabolism of leukocytes, bacteria, or tumor cells or hydrogen ion accumulation.

Box 69-3 Conditions Commonly Associated With Low-pH and Low-Glucose Pleural Effusions*

Empyema
Complicated parapneumonic effusion
Malignant effusion
Rheumatoid pleuritis
Tuberculosis
Lupus pleurisy
Esophageal rupture
Urinothorax (transudate)

*Low-pH effusions: pH <7.3; low-glucose effusions: <3.3 mmol/L (60 mg/dL).

In malignant pleural effusions, a low pH is associated with more extensive tumor involvement of the pleura, a higher chance of positive findings on cytologic examination, a lower success rate for pleurodesis, and a poorer prognosis. In parapneumonic effusion, a low pH (less than 7.2) predicts the need for chest tube drainage, and pH below 7.2 is now often used as a cutoff point to diagnose pleural infection (complicated parapneumonic effusion) in the presence of a compatible clinical history. A recent study of 308 patients confirmed that pleural fluid pH (or glucose) measurements were superior to other biomarkers tested (pleural fluid procalcitonin, C-reactive protein, lipopolysaccharide-binding protein, and triggering receptor expressed on myeloid cells-1 [sTREM-1]) in distinguishing between simple and complicated parapneumonic effusions.

Disease-Specific Tests

The diagnosis of a malignant effusion should be established only by histocytopathologic confirmation of malignant cells in the pleural fluid or tissue. Pleural fluid cytologic examination is the first line of investigation in suspected cases and has a sensitivity up to 60% (dependent on tumor type, extent of disease, and experience of the cytologist). Immunocytochemical analysis plays an invaluable role in cytologic assessment of pleural fluid, improving the differentiation between benign and malignant effusions and between different malignancies (particularly metastatic adenocarcinoma versus mesothelioma). If malignancy is suspected, generally little incremental benefit is obtained from cytologic analysis of pleural fluid on more than two occasions.

Mesothelioma, the most common primary malignant tumor of the pleura, often is challenging to diagnose. Research in recent years has proposed several potential adjunct diagnostic biomarkers. Mesothelin is a U.S. Food and Drug Administration (FDA)-approved diagnostic and prognostic marker for mesothelioma, although it is not recommended as a sole diagnostic marker (having sensitivity of 48% to 84% and specificity of 70% to 100%). False-negative results may occur with sarcomatoid mesothelioma, which often does not express mesothelin. A raised mesothelin level also can be found with other malignancies (most commonly, pancreatic or ovarian carcinoma but also lung adenocarcinoma and lymphoma). Hence, in patients with elevated pleural fluid or blood mesothelin, further investigations should be considered even if cytologic examination demonstrates no malignant cells. Megakaryocyte-potentiating factor (MPF), which originates from the same precursor protein as for mesothelin, has been shown to have a similar diagnostic performance for detection of mesothelioma. After initial interest in the use of osteopontin for mesothelioma identification, subsequent data have shown it to have a lower diagnostic accuracy than mesothelin.

Other tumor markers and pleural fluid cytokine measurements are neither sensitive nor specific enough for clinical use. Cytogenetic evaluation may be a helpful addition to characterize chromosomal markers of hematolymphoid and mesenchymal malignancies. Flow cytometry of the pleural aspirate should be considered if lymphoma is a possibility.

Gram staining and culture of pleural fluid should be performed in an appropriate clinical setting. Direct inoculation of bottled culture media ("blood culture bottles") along with separate microbiologic analysis of pleural fluid in a universal container has been shown to increase microbial yield. In cases characterized by presence of frank pus, the diagnosis of empyema is secured, but Gram staining and culture may help to identify the causative organism(s) and to guide therapy.

Testing for tuberculosis should be conducted if clinically indicated, particularly if the fluid is lymphocyte-predominant (more than 50% of total leukocytes). Direct smears and aspirate cultures have low sensitivities (less than 5% and 10% to 20%, respectively) because tuberculous pleuritis usually develops as a type IV hypersensitivity reaction, with low mycobacterial load in the pleural cavity. Demonstration of caseating granulomas by closed or thoracoscopic pleural biopsy clinches the diagnosis. Debate exists regarding the role of adenosine deaminase (ADA), interferon-γ, interferon-γ release assays (IGRAs), and polymerase chain reaction (PCR) techniques in diagnosing tuberculous pleuritis. ADA, an enzyme present in lymphocytes, commonly is measured in disease-endemic countries, and a high pleural fluid ADA level suggests tuberculous effusions, with a sensitivity of greater than 90%. False-positive results have been reported (especially with empyema, rheumatoid effusions, and lymphoma). In nonendemic areas, a low ADA measurement may help rule out tuberculous pleuritis in some patients. Assays for the isoenzyme ADA_2, which predominates in tuberculous effusions, are not widely available. Unstimulated interferon-γ pleural fluid levels perform about as well as ADA for diagnosis in this setting but are more expensive. Peripheral blood and pleural fluid IGRAs have been shown to be of limited clinical value in the diagnosis of tuberculous pleural effusions.

A raised amylase level (above the serum upper limit of normal or if the pleural fluid–to–serum ratio is more than 1) in an appropriate clinical setting can help confirm effusions from esophageal rupture and pancreatic diseases (acute pancreatitis or pseudocyst). Isoenzyme analysis may further differentiate the source of amylase (salivary or pancreatic) but is rarely needed. A raised amylase is present in some malignant (usually adenocarcinomas) effusions.

In suspected cases of chylothorax, lipoprotein electrophoresis for chylomicrons or a triglyceride concentration greater than 1.24 mmol/L (110 mg/dL) confirms the diagnosis. The presence of cholesterol crystals at microscopy with a pleural fluid cholesterol level more than 5.17 mmol/L (200 mg/dL) is diagnostic of a pseudochylothorax. Chylomicrons are not found in pseudochylothorax fluid.

Pleural fluid levels of rheumatoid factor and antinuclear antibody mirror serum values and add little to clinical management of rheumatoid or systemic lupus erythematosus–related pleuritis. Complement levels can be reduced but are of little clinical value. Very low pleural fluid glucose levels typically are seen in patients with a rheumatoid effusion, and differentiation from empyema fluid may be difficult.

β_2-Transferrin is found in cerebrospinal fluid, and its presence in pleural fluid confirms presence of a duropleural fistula. Raised creatinine values are seen in urinothorax.

PLEURAL BIOPSY

Histologic examination (with or without culture) of pleural tissue can aid in the diagnosis of specific pleural diseases. Tissue can be collected percutaneously (by "blind" or imaging-guided biopsy) or under direct vision (by thoracoscopy or thoracotomy), each with its relative merits (see Chapters 13 and 74).

Percutaneous Biopsy

"Blind" percutaneous pleural biopsy (performed using an Abrams or Cope needle) has been shown to be inferior to imaging-guided biopsy for the diagnosis of malignancy in a randomized controlled trial. Blind biopsy can still be useful in diagnosing diseases with diffuse pleural involvement, especially granulomatous pleuritis (e.g., from TB or rheumatoid arthritis), particularly if thoracoscopic facilities are not readily available. The yield, however, is critically dependent on operator experience and also on the number of passes.

Thoracoscopy

Thoracoscopy is indicated in patients with an undiagnosed exudative pleural effusion after a nondiagnostic thoracentesis. Thoracoscopy can be performed by physicians or surgeons either using local anesthesia and sedation (pleuroscopy) or with the patient under general anesthesia using single-lung ventilation (video-assisted thoracoscopic surgery, [VATS]). Pleuroscopy allows direct visualization of almost the entire pleural surface (**Figure 69-9**), drainage of fluid, parietal pleural biopsy, and pleurodesis by talc poudrage in the same procedure. Diagnostic sensitivity approaches 95% in malignant pleural diseases and almost 100% in tuberculous pleurisy. Complications are few, and mortality rates low (less than 0.5%). VATS has a similarly high diagnostic sensitivity but also allows other invasive interventions during surgery, including lung biopsy. For details of the technique, refer to Chapter 74.

Thoracotomy

Open biopsy with thoracotomy is now seldom indicated. It is a more invasive procedure with significant morbidity, especially postthoracotomy pain.

TREATMENT

Therapeutic objectives in patients with a pleural effusion include treatment of underlying disease, palliation of symptoms, and prevention of fluid recurrence.

MANAGEMENT OF THE UNDERLYING CAUSE

Optimizing the management of the underlying cause (e.g., appropriate diuretic therapy in patients with congestive cardiac failure) is adequate for some effusions. In certain instances (e.g., malignant effusions), however, the underlying cause may not be treatable, and other strategies to prevent reaccumulation of pleural effusions are needed.

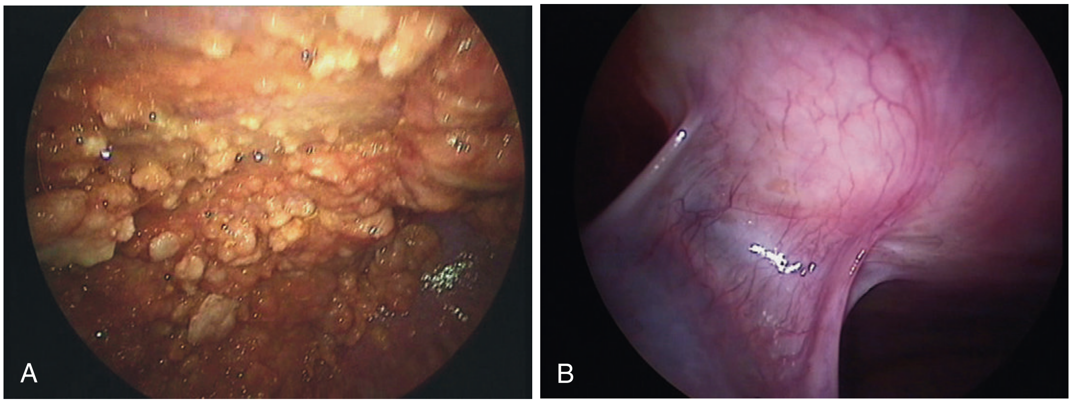

Figure 69-9 **A,** Thoracoscopic view into the right pleural cavity showing multiple tumor nodules covering the parietal pleura. **B,** Thoracoscopy allows identification and biopsy of pleural abnormalities under direct vision while avoiding potentially hazardous structures (e.g., highly vascularized adhesion).

SYMPTOM CONTROL

Thoracentesis

Therapeutic pleural aspiration can be performed at the bedside to relieve breathlessness. For recurrent effusions (e.g., malignant pleural effusions), a definitive procedure to stop fluid reaccumulation, such as pleurodesis, should be considered. If this fails, repeat thoracenteses may be necessary for palliation of breathlessness.

Placement of Indwelling Pleural Catheters

The insertion of a long-term tunneled indwelling pleural catheter (IPC) allows outpatient drainage of refractory malignant pleural effusions. The ambulatory catheters can be inserted as a "day case," avoiding the need for hospital admission. Its presence induces a complete or partial pleurodesis in up to 70% of patients, and the patient (or the caregiver) can drain the effusion as guided by symptoms, averting hospitalization. Implantation of an IPC also is indicated in patients with a symptomatic effusion and underlying trapped lung, as described later. The catheters usually are well tolerated in clinical practice, but reported complications include development of pleural septations, pleural or soft tissue infection, local tumor invasion at the insertion site, and catheter displacement (Figure 69-10). A randomized trial is under way to evaluate the use of IPCs as first-line therapy in malignant effusions.

Insertion of a pleuroperitoneal shunt is another alternative if pleurodesis fails. This intervention is contraindicated in the presence of ascites, and potential complications include infection and shunt occlusion (approximately 10%).

Noninvasive Palliation

In terminally ill patients with symptomatic effusions, use of opiates and oxygen therapy to alleviate breathlessness may be appropriate.

PREVENTING FLUID REACCUMULATION

Pleurodesis

The dual aim of pleurodesis is to achieve fusion between the visceral and parietal pleural surfaces and to prevent reaccumulation of pleural fluid (or air). It is indicated in symptomatic malignant pleural effusions and occasionally for recurrent benign effusions when other treatments fail. Dyspnea in patients with malignant effusions often is multifactorial. Only patients with symptomatic improvement consequent to evacuation of the effusion should be considered for pleurodesis.

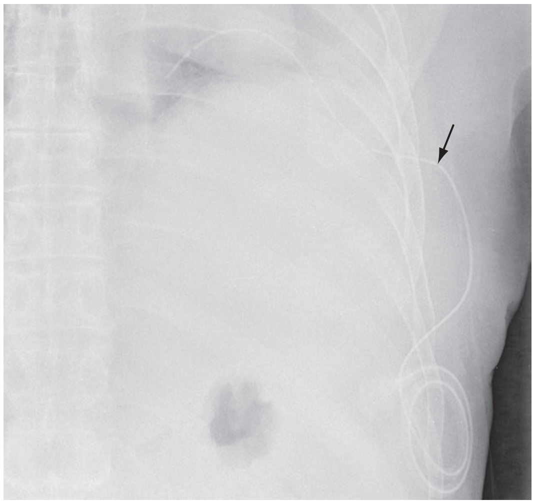

Figure 69-10 Magnified chest radiograph demonstrating a left-sided indwelling pleural catheter (IPC), which has become partly displaced and now has a drainage hole within the subcutaneous tissues (*arrow*).

To achieve successful pleural symphysis, pleural fluid is drained to allow apposition of the pleural layers. Fluid can be drained either at thoracoscopy or using a chest tube. Use of smaller-bore chest tubes (10 to 14F) is associated with less discomfort and allows equal pleurodesis efficacy compared with larger tubes. Pleurodesis, accomplished by mechanical abrasion or using chemical agents, aims to induce damage to the pleura. The resultant acute pleural inflammation, if sufficiently intense, will progress to chronic inflammation with consequent development of pleural adhesions and fibrosis. Pain and fever are common, secondary to the inflammatory process. In animal studies, dampening of this inflammatory process with corticosteroids inhibits pleurodesis. Whether this applies in humans remains unclear.

Pleurodesis is not indicated if close contact of the pleural layers cannot be achieved. The presence of a so-called *trapped lung,* when lung expansion is restricted either by visceral pleura tumor encasement or by endobronchial obstruction, prohibits effective pleurodesis (Figure 69-11). With "entrapment" of a significant (greater than 50%) proportion of the lung, insertion of an indwelling pleural catheter should be considered.

Talc is the most commonly used pleurodesis agent worldwide. It can be insufflated as a dry powder (poudrage) during thoracoscopy or instilled through a chest tube as a slurry, with similar efficacy of approximately 75% in a large randomized

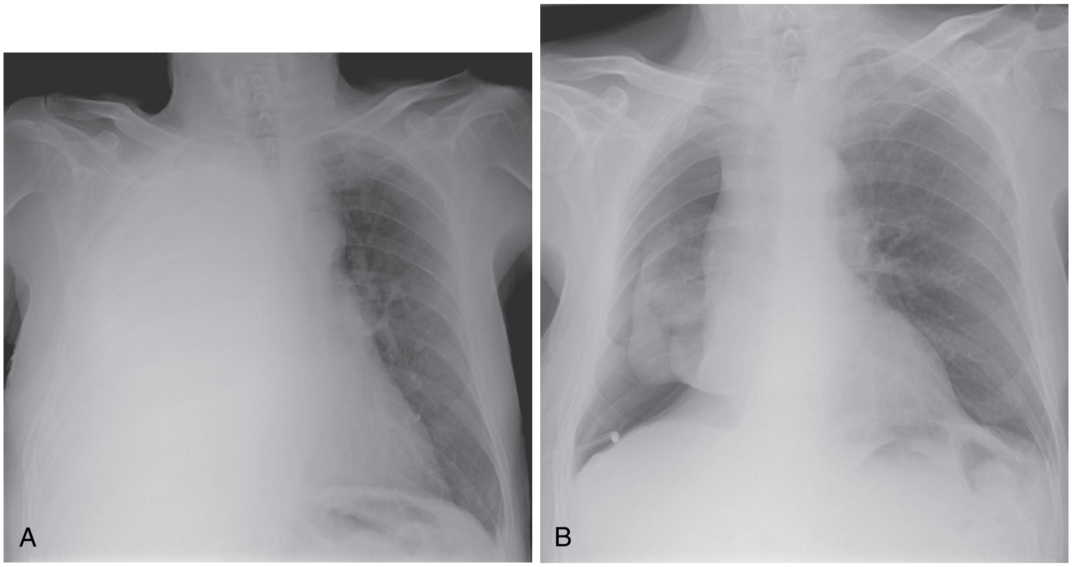

Figure 69-11 Radiographic appearance of trapped lung. The patient had bronchogenic adenocarcinoma and initially was seen with a massive right-sided pleural effusion causing mediastinal shift (**A**). After pleural drainage (with an intercostal tube in situ), his lung failed to reexpand (**B**). Recognizing the presence of trapped lung is important, because pleurodesis not only is unlikely to be successful but may induce visceral fibrosis, causing further restriction of the underlying lung.

study of 482 patients. Adverse effects (e.g., pain, fever) are common after talc pleurodesis and can be serious. The incidence of reported talc-induced acute respiratory distress syndrome (ARDS) ranges from 0 to 9%, and its mechanism remains poorly understood. Particle size, presence of contaminants, and reexpansion pulmonary edema have all been implicated. A randomized controlled trial has confirmed that nongraded talc preparations with “small” particle size (less than 15 µm median diameter) led to more systemic and pulmonary inflammation with resultant hypoxemia. A subsequent study using larger-particle graded talc found no evidence of associated ARDS. In patients with preexisting respiratory compromise, alternative agents (e.g., doxycycline or bleomycin) should be considered. Other agents such as povidone-iodine, silver nitrate, and OK432 are used in some centers.

SPECIFIC ENTITIES ASSOCIATED WITH PLEURAL EFFUSION

CONDITIONS ASSOCIATED WITH TRANSUDATIVE EFFUSIONS

Congestive Cardiac Failure

Effusion secondary to congestive cardiac failure accounts for most transudative effusions worldwide. It is also the most common cause of pleural effusions necessitating acute medical hospital admissions, and as many as 50% to 75% of the hospitalized patients will have pleural effusions, commonly bilateral. Such effusions are thought to arise from transpleural migration of pulmonary interstitial fluid accumulated from elevated pulmonary capillary pressure.

Clinical history and physical examination usually secure the diagnosis. Chest radiography commonly reveals bilateral effusions, cardiomegaly, and venous congestion.

Management is directed at the underlying congestive cardiac failure. Pleurodesis has been performed in refractory cases with variable success. If the patient fails to respond to diuresis or other, atypical features (i.e., unilateral effusion, massive pleural effusion, or fever) are present, further investigation is warranted.

Occasionally, the pleural fluid may be classified as an exudate using Light’s criteria, probably arising because of differential drainage of fluid over protein molecules from the pleural space as a result of diuretic therapy. A plasma-to-effusion protein gradient of more than 3.1 g/dL suggests that the fluid originally formed as a transudate. N-terminal (amino-terminal) pro-brain natriuretic peptide (NT-proBNP) is a sensitive marker of cardiac failure, in both blood and pleural fluid, and can be used to avoid repeated investigations in patients with exudative effusions suspected to be originally caused by cardiac failure. In patients with bilateral transudative pleural effusions with pulmonary hypertension and normal left ventricular function, pulmonary venoocclusive disease (PVOD) should be considered.

Hepatic Hydrothorax

Hepatic hydrothorax occurs in approximately 5% of patients with liver cirrhosis and portal hypertension. Pleural effusions accumulate from transdiaphragmatic migration of ascitic fluid. Fluid also accumulates from the decreased oncotic pressure associated with secondary hypoalbuminemia, and extremely rarely from hemorrhage of congested collateral veins. Most hepatic hydrothoraces are right-sided, and concomitant ascites is frequent but is not a prerequisite. The diagnosis is based on the presence of cirrhotic liver disease, ascites, and transudative fluid on thoracentesis. Spontaneous bacterial empyema may occur and, even with prompt recognition, carries a mortality rate ranging up to 20%.

Management should be directed at treating portal hypertension and reducing the volume of ascitic fluid with diuretic therapy and sodium restriction. This approach frequently fails, and therapeutic thoracenteses may be indicated for symptomatic relief. Loss of electrolytes and protein is a concern. Pleurodesis may be tried in therapy-resistant cases, and repair of any diaphragmatic defects attempted at thoracoscopy. Use of concomitant continuous positive airway pressure (CPAP)

Table 69-3 **Characteristics of Simple and Complicated Parapneumonic Effusions and Empyema**

Feature	Simple Parapneumonic Effusion	Complicated Parapneumonic Effusion	Empyema
Appearance	Clear/slightly turbid	Often cloudy	Pus
pH	≥7.20	<7.20	Not measured
Glucose*	≥2.2 mmol/L (40 mg/dL)	<2.2 mmol/L (40 mg/dL)	Not measured
Lactate dehydrogenase (LDH)	≤1000 U/L	>1000 U/L	Not measured
Bacteria on Gram stain or culture	No	~25%	~70%

*Glucose threshold advocated in latest British Thoracic Society guidelines, although previous American College of Chest Physicians guidelines suggested 3.3 mmol/L (60 mg/dL).

ventilation at the time of pleurodesis to reverse the peritoneal-pleural gradient has been successful in case reports but remains experimental at present. Transjugular intrahepatic portosystemic shunting (TIPS) can relieve symptomatic hepatic hydrothorax, but liver transplantation, in selected patients, is the only definitive therapy.

Renal Effusions

Pleural effusions may arise in association with nephrotic syndrome, acute glomerulonephritis, or peritoneal dialysis. Transdiaphragmatic migration of peritoneal dialysate often results in a right-sided effusion chemically resembling the dialysis fluid.

Urinothorax is rare but should be considered whenever a low-pH transudative effusion is encountered in clinical practice. It arises secondary to renal obstruction with resultant retroperitoneal urine collection and transfer into the ipsilateral pleural cavity, or a fistula draining into the pleural cavity. An ammonia-like smell is diagnostic, and increased fluid-to-serum creatinine levels are confirmatory.

CONDITIONS ASSOCIATED WITH EXUDATIVE EFFUSIONS

Parapneumonic Effusion and Empyema

Pleural effusions occur in up to 57% of patients with pneumonia and range in size from small subcentimeter effusions to large effusions causing ventilatory embarrassment. A majority of these (approximately 60%) are sterile “simple” parapneumonic effusions reflecting vascular hyperpermeability from pleural inflammation secondary to the underlying pneumonia. “Complicated” parapneumonic effusions are characterized by neutrophilia, low pH and glucose, and often fibrinous septations (caused by fibrin deposition within the procoagulant milieu of the infected pleural space). The current belief is that complicated pleural effusion represents one end of the spectrum of pleural infection and should be treated as such. At the other end of the spectrum is empyema, characterized by frank pleural pus or presence of bacteria in the pleural fluid (Table 69-3).

Differentiation between simple and complicated effusions is important, because an infected pleural space requires prompt pleural drainage, being associated with significant morbidity and mortality (15% of patients require surgery, and up to 20% die). Parapneumonic effusion should be suspected in all patients with pneumonia, particularly those in whom clinical improvement fails to occur or laboratory markers of infection remain persistently abnormal. Patients with diabetes mellitus, alcohol or substance abuse, coexisting chronic lung disease, immunosuppression, or rheumatoid arthritis have a higher incidence of pleural infection. Poor dental hygiene is more prevalent in those with anaerobic infection. A low serum albumin less than 30 g/L, C-reactive protein more than 100 mg/L, platelet count more than 400 × 10^9/L, serum sodium less than 130 mmol/L, intravenous drug use, and alcohol misuse have been shown to be associated with development of complicated parapneumonic effusion in patients with pneumonia. Recent novel genetic studies also suggest that a variant of the protein tyrosine phosphatase (PTPN22 Trp620) is associated with susceptibility to invasive pneumococcal disease and gram-positive empyema. Primary empyema, in the absence of pneumonia, is responsible for 4% of pleural infection cases.

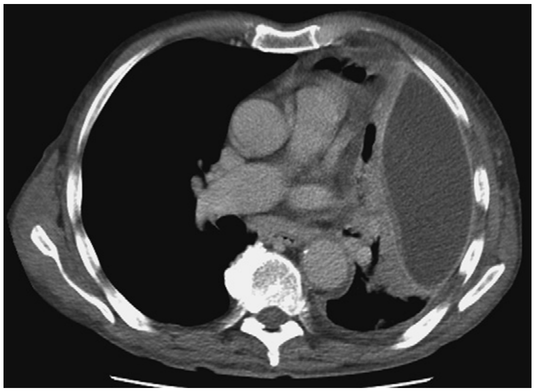

Figure 69-12 A contrast-enhanced computed tomography image of pleural empyema. The “split pleura” sign is demonstrated, with enhancement of both the visceral and the parietal pleural surfaces evident. *(Courtesy Dr. Rachel Benamore, Oxford, United Kingdom.)*

Chest radiography usually identifies the pleural collection and concomitant pneumonia. In a patient with sepsis, the finding of a new encapsulated effusion in a nonbasal position is strongly suggestive of pleural infection. Ultrasound imaging is of value in the evaluation of pleural infection, allowing fluid characterization and localization (which is particularly important for loculated fluid). In a patient with signs of infection, septations on ultrasound images suggest an infected pleural space with low pH, low glucose, and high lactate dehydrogenase (LDH); heavily echogenic fluid usually represents pus (or blood). Of note, however, the converse does not hold; absence of such sonographic features does not rule out pleural infection. Pleural-phase CT provides detailed information and discriminates between empyema and lung abscess. Empyemas usually are lenticular in shape, with compression of surrounding lung parenchyma. The “split pleura” sign, with enhanced parietal and visceral pleural tissue visible as the surfaces are separated by the pleural collection, is characteristic (Figure 69-12). Pleural thickening is seen in 86% to 100% of empyemas and in 56% of parapneumonic effusions. Pleural enhancement and increased attenuation of the extrapleural subcostal fat are suggestive of an infected pleural space.

Frankly purulent or malodorous fluid confirms presence of an empyema. If not purulent on gross examination, the pleural fluid pH should be assessed. A pH less than 7.2, or reduced fluid glucose, indicates a complicated parapneumonic effusion. Positive Gram staining or fluid culture confirms pleural infection and can guide antibiotic choice but is positive in only about 50% to 60% of patients. The use of genetic microbiologic testing to allow organism identification (using PCR and sequencing of the bacterial 16S ribosomal RNA gene) is under investigation. Treatment of complicated parapneumonic effusions or empyema includes appropriate antimicrobial therapy, optimal nutritional support, venothromboembolism prophylaxis, and evacuation of the infected pleural fluid (by chest tube or surgery).

Bacteriology

It is important to differentiate between community- and hospital-acquired pleural infection, because the bacteriology and prognosis differ for the two types. Hospital-acquired cases often are iatrogenic or secondary to hospital-acquired pneumonia and carry a mortality rate several times higher than that for community-acquired cases. The microbiology also varies geographically. In the United Kingdom, gram-positive streptococci account for most community-acquired cases of pleural infection, with the *Streptococcus milleri* group (*Streptococcus constellatus*, *Streptococcus intermedius*, *Streptococcus anginosus*) accounting for 24% and *Streptococcus pneumoniae* causing 21%. *Staphylococcus aureus* is isolated in 10% of the cases. Gram-negative organisms, such as *Haemophilus influenzae*, *Escherichia coli*, *Pseudomonas* spp., and *Klebsiella* spp. occur in about 10% of cases, particularly in patients with comorbid conditions such as diabetes. Anaerobic pathogens are detected in 12% to 34% of cases, although some studies suggest a much higher incidence. With hospital-acquired infection, methicillin-resistant *Staphylococcus aureus* (MRSA) is responsible for more than a quarter of cases of pleural infection, and gram-negative organisms such as *E. coli*, *Enterobacter* spp., and *Pseudomonas* spp. are common and particularly associated with critical illness necessitating admission to an intensive care unit.

Antibiotics

All patients should receive antibiotic therapy. Empirical treatment should be initiated while awaiting bacterial culture results and must take into account where the infection was acquired (hospital or community), patient comorbid conditions, and local bacterial resistance patterns. A common antibiotic choice to cover community-acquired pathogens is a beta-lactam antibiotic in conjunction with a beta-lactamase inhibitor (such as amoxicillin and clavulanic acid) or piperacillin-tazobactam. Metronidazole usually is given as well, to ensure adequate anaerobic coverage. Given that hospital-acquired pleural infection is more likely to be caused by resistant pathogens, including gram-negative enteric bacteria and MRSA, a reasonable antibiotic selection in such patients is a carbapenem with vancomycin. Therapy may be modified in the light of positive culture and sensitivity results. Prolonged courses of antibiotics (e.g., 4 to 6 weeks) often are required.

Drainage

Simple parapneumonic effusions generally do not require drainage, but drainage of complicated effusions and empyema is key to their management.

Loculation is common in pleural infection, and imaging-guided insertion of chest drains can ensure optimal placement. Selection of appropriate chest tube size remains contentious, with no randomized trial evidence available, although recent studies have suggested that smaller (less than 15F) Seldinger inserted tubes are less painful, are associated with fewer complications, and perform as well as larger, blunt dissection–inserted tubes. Instillation of intrapleural fibrinolytic agents for complex parapneumonic effusions or empyema has been proposed to disrupt fibrinous septations and potentially improve drainage. However, a large multicenter study, the first Multicenter Intrapleural Sepsis Trial (MIST1), with 454 subjects, failed to demonstrate a benefit on mortality statistics, need for surgery, or duration of hospital stay for patients who received intrapleural streptokinase. A 2008 Cochrane review examining seven fibrinolytic studies concluded that use of fibrinolytics conferred no significant benefit in reducing surgical requirements. The recent MIST2 study examined combination fibrinolytic-plus-DNase therapy in a 2 × 2 factorial randomized controlled trial of tissue-type plasminogen activator (tPA) and deoxyribonuclease (DNase) in 210 patients. This study found that combination tPA and DNase significantly improved pleural fluid drainage (primary outcome) and led to a reduced rate of surgical referral and shorter hospital stay (secondary outcomes), although further studies are needed to define the size of treatment effects.

Prompt referral for surgical drainage is indicated in the 30% of patients who have ongoing sepsis with chronic pleural fluid effusion despite optimal medical treatment. Secondary pleural thickening (fibrothorax) is seen in less than 10%; in this setting, however, residual pleural thickening and lung function impairment always lessen with time and are not indications for surgery. VATS is preferred, but more invasive procedures (e.g., thoracotomy or rib resection with open drainage) are sometimes needed.

Use of VATS as first-line treatment of pleural infection remains contentious, with randomized studies in adults and children failing to show a significant difference in mortality or major morbidity with VATS. Adult studies have shown a shorter hospital stay with VATS (approximately 11 versus 8 days), but a pediatric study showed no difference in length of stay (primary outcome) but a higher cost of VATS.

PLEURAL INFECTION IN CHILDREN

Significant differences exist between pleural infection in children and that in adults in both clinical course and prognosis; the reasons for the differences remain unclear. Pediatric empyema has an incidence of 3.3 per 100,000, and evidence suggests that this rate is rising in many countries. Most cases are secondary to underlying bacterial pneumonia, and *S. pneumoniae* is most commonly isolated. Since the licensing of the 7-valent pneumococcal conjugate vaccine (PCV7) in 2000, active against serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F, the accumulating evidence shows that the nonvaccine serotype 1 is causing increasing numbers of cases of empyema and other invasive pneumococcal disease in some areas.

The diagnosis is based on clinical findings and chest radiography or ultrasonography confirming a pleural collection. Thoracentesis and chest tube drainage may be difficult in babies and young children and usually necessitate use of general anesthesia. Management with adequate fluid therapy, intravenous antibiotics, and antipyretics is sufficient in many cases, and liaison with a tertiary pediatric respiratory care unit is recommended. Advocates of early surgical intervention suggest that if a child is undergoing general anesthesia for chest drain insertion, a definitive procedure such as VATS débridement should be performed; however, no consensus exists. The prognosis in children with empyema is significantly better than that in adults.

TUBERCULOUS PLEURAL EFFUSIONS

Tuberculous pleural effusions represent either primary pleural mycobacterial infection or reactivation of latent infection. Most cases of tuberculous pleuritis develop as a result of a delayed hypersensitivity reaction to the mycobacterial protein, rather than from mycobacterial invasion. The number of organisms within the pleural space often is low.

Acute clinical presentation with pleuritic chest pain and fever is uncommon; more typically, symptoms develop insidiously, with gradual onset of dyspnea and constitutional features. Chest radiographs reveal a pleural effusion with or without parenchymal infiltrates. The pleural fluid is lymphocytic in more than 90% of cases, and fluid glucose and pH may be low. Samples should be sent for staining for acid-fast bacilli and culture for the TB pathogen, although the diagnostic yield usually is low. Obtaining tissue for culture and a histologic diagnosis is important; caseating granulomas frequently are used as a diagnostic surrogate when culture is negative. Because involvement of the pleura in TB commonly is generalized, percutaneous “blind” pleural biopsy is sensitive, although thoracoscopy may further increase yield. The parietal pleura usually have a characteristic appearance of disseminated fine nodules.

Adenosine deaminase (ADA) levels have a high sensitivity and specificity and are routinely used in many countries in which TB is endemic. Low ADA concentrations make tuberculous pleuritis unlikely. High levels also occur in empyema, malignancy (e.g., lymphoma), and collagen vascular diseases.

Spontaneous resolution frequently is seen in tuberculous effusions irrespective of antimycobacterial chemotherapy. Without appropriate treatment, however, approximately 60% of patients will have clinically overt TB develop elsewhere within 5 years. Mycobacterial resistance patterns in cases of tuberculous pleuritis usually are similar to the local resistance patterns of pulmonary TB cases. The treatment of TB is covered in Chapter 31. Thoracentesis may aid symptom relief, and steroids may help to reduce fluid volume, but neither alters the long-term outcome or the incidence of fibrothorax.

PLEURAL EFFUSIONS SECONDARY TO INFECTIONS WITH OTHER ORGANISMS

Viruses, legionnaires disease, *Mycoplasma*, and *Rickettsia* spp. may be associated with pleural effusion in approximately 20% of cases, although they usually are small simple effusions that resolve without needing drainage. The diagnosis is made clinically, with serologic tests, urinary antigen detection (legionnaires disease), or on culture. Pleural fluid commonly is lymphocytic, although neutrophils initially may predominate.

Pulmonary nocardiosis may be complicated by empyema in up to a quarter of cases, and empyema frequently is seen in patients with pulmonary actinomycosis.

Mycotic lung disease accounts for less than 1% of all pleural effusions and usually occurs in immunocompromised hosts. *Candida albicans* is the most common pathogen in fungal empyema and is associated with a high (greater than 70%) mortality rate. Prompt treatment with systemic antifungal agents and pleural drainage is required. In approximately 4% of patients with (human) blastomycosis and 20% with respiratory coccidioidomycosis, pleural effusions are observed. These generally resolve spontaneously without specific treatment. *Pneumocystis jirovecii* infection is rarely associated with pleural effusion in the immunocompromised host.

Amebic disease can result in empyema, hepatobronchial fistula formation, or a pleural effusion secondary to perforation of an amebic liver abscess. Pleural effusions related to other parasitic infections are extremely rare.

MALIGNANT PLEURAL EFFUSIONS

Malignant pleural effusions (MPEs) are common and affect 660 patients per 1 million population per year. They account for 22% of all pleural effusions and in 20% of patients constitute the presenting manifestation of malignancy. The most common cytologic diagnoses in developed countries are metastatic breast or lung carcinoma, lymphoma, and mesothelioma. Most malignant tumors can metastasize to the pleura. Up to 50% of patients with breast cancer, a quarter of those with bronchogenic carcinoma, and more than 95% of patients with mesothelioma will develop a pleural effusion during their disease course. Symptoms with MPE can be severe, and successful symptom control can contribute to significantly improved quality of life.

Pleural fluid accumulates as a result of increased fluid formation and reduced lymphatic drainage (from malignant involvement of parietal lymphatic channels or mediastinal lymphadenopathy). In some patients with underlying malignancy, a pleural effusion may develop without direct pleural involvement. Such “paramalignant” effusions may be caused by pulmonary embolism, pneumonia, secondary atelectasis, pericardial tumor involvement, hypoproteinemia, or radiotherapy-induced inflammation. Although the distinction is important in cases in which curative resection is considered, some studies have shown that patients with a paramalignant effusion have a prognosis similar to that in persons with frank malignant effusions.

Positive histocytologic confirmation is required for diagnosis. Pleural fluid cytologic examination establishes proof in approximately 60% of the cases, and if findings are negative, thoracoscopy or CT-guided pleural biopsy (if focal pleural abnormality is evident on CT scan) is the logical next step.

Except for a small number of chemotherapy-sensitive tumors (e.g., lymphoma), cure of the underlying malignancy usually is not possible once the cancer has metastasized to the pleura. Management is therefore directed toward controlling symptoms and improving quality of life. Various options are available (as described earlier under “Treatment”); the most appropriate interventions will depend on the patient’s symptoms, performance status, and expected survival.

EFFUSIONS SECONDARY TO CONNECTIVE TISSUE DISEASE

Rheumatoid Arthritis

Pleural effusions are the most common thoracic manifestation of rheumatoid arthritis and occur in up to 5% of patients, more frequently men (70%). Often the effusions develop several years after the original diagnosis and in 30% of the cases arise concomitantly with interstitial lung disease or rheumatoid lung nodules. The effusion may persist for years, although spontaneous resorption occasionally is observed. Symptomatic recurrent effusions are rare and may respond to systemic corticosteroid therapy.

Distinguishing rheumatoid effusions from empyema or pseudochylothorax is important but can be difficult. Pleural fluid from a rheumatoid effusion is characterized by leukocytosis, a low glucose, low pH, and increased LDH—features indistinguishable from those of pleural infection. Low complement and elevated pleural fluid rheumatoid factor levels are not diagnostic.

Systemic Lupus Erythematosus

Fifty percent of patients with systemic lupus erythematosus (SLE) will have a pleural effusion, often bilateral and typically exudative (occasionally hemorrhagic), with a lymphocytosis (if the effusion is chronic). Nonsteroidal antiinflammatory medication may relieve pleuritic chest pain, and corticosteroid treatment results in a swift clinical response if the patient remains symptomatic. Pleural effusions arising as a consequence of drug-induced lupus erythematosus are rare.

Other Connective Tissue Disorders

Granulomatosis with polyangiitis (Wegener's) is associated with pleural effusion in approximately 30% of patients and responds to treatment of the underlying condition with immunosuppressant therapy. Pleural effusion may occur in up to 30% of those with Churg-Strauss syndrome; typically, the fluid is rich in eosinophils. The effusions usually are not of any clinical consequence, and most resolve with corticosteroid therapy.

EFFUSION FROM VASCULAR CAUSES

Pleural effusions occur in up to 50% of patients with pulmonary embolism. This diagnosis often is overlooked and should be considered in any patient with an undiagnosed pleural effusion. The pathophysiology remains under debate, and no specific diagnostic features are recognized. Physicians should maintain a high index of clinical suspicion for pulmonary emboli, particularly when other etiologic disorders have been excluded. Effusions normally are exudative, usually are small, and can be blood-stained. Standard treatment of pulmonary emboli should be initiated. The pleural effusion seldom needs drainage and usually will resolve over time.

Effusions after coronary artery bypass graft surgery are common, and in most cases, spontaneous resolution occurs within 6 months. Postcardiac injury syndrome (Dressler syndrome) after myocardial infarction or bypass surgery can result in small bilateral effusions and seldom requires intervention. Sickle cell anemia–related acute chest syndrome results in pleural effusion in 30% to 35% of cases.

DRUG-INDUCED PLEURAL EFFUSIONS

Drug-induced pleural effusions do occur, and a careful drug history may be required to make a diagnosis. Various prescribed medications, including amiodarone, nitrofurantoin, methotrexate, bromocriptine, clozapine, and phenytoin, may result in exudative pleural effusions and eventual pleural fibrosis (see www.pneumotox.com for further causes of drug-induced effusions). Withdrawal of the offending drug, with use of corticosteroids if needed, is sufficient in many cases. Decortication has been attempted but is of no established benefit.

Ovarian hyperstimulation syndrome (OHSS) is an iatrogenic complication occurring in approximately 3% of women undergoing therapeutic ovarian stimulation. It is becoming increasingly recognized as higher numbers of women undergo assisted reproduction procedures, and the exact pathogenesis remains unclear. OHSS is characterized by ovarian enlargement and rapid fluid shifts secondary to increased capillary permeability, which result in intravascular volume depletion. In severe cases, massive ascites with hydrothorax can arise. The treatment is primarily supportive, but fatal cases have been reported.

EFFUSIONS RELATED TO ABDOMINAL DISEASES

Pleural effusions occur in approximately 20% of patients with acute pancreatitis; two thirds are left-sided, and pleural fluid amylase concentrations exceed serum values. Pancreatic pseudocyst, pancreatic-pleural fistula, and abscess formation must be considered if the effusion persists. Effusions also accompany subphrenic abscess in more than 50% of patients. Cholohemothorax secondary to gallstone perforation into the pleural cavity is extremely rare and results in a bilious effusion.

Effusions arising after abdominal surgery are common, and investigation is rarely required, provided secondary infection is excluded.

Meigs syndrome consists of the combination of benign ovarian tumors and coexisting pleural effusion and ascites. These features resolve after tumor resection.

Hemothorax

Hemothorax is characterized by pleural fluid hematocrit values greater than 50% of peripheral blood. The main causes are trauma, iatrogenic (most commonly after thoracic surgery) factors, malignancy, anticoagulation therapy, pulmonary infarction, and aortic rupture. Complications include empyema (1% to 4% of traumatic hemothoraces), trapped lung, and fibrothorax. Treatment is guided by the clinical scenario, but tube thoracostomy to enable evacuation of the blood and assessment of the extent of hemorrhage is advised. Surgical intervention (preferably VATS) is indicated if the bleeding rate is greater than 200 mL/hour. Prophylactic antibiotics usually are administered, although literature evidence to support this practice is scarce.

Chylothorax

Chylothorax develops when disruption of the thoracic duct results in passage of chyle (lymph rich in chylomicrons) into the pleural cavity. The pleural fluid characteristically is milky in appearance (Figure 69-13), except in starved patients. Chylothorax must be differentiated from pseudochylothorax and empyema fluid (see under "Pleural Fluid Analysis").

Trauma is the most common cause of chylothorax, which is predominantly iatrogenic secondary to thoracic duct damage during cardiothoracic surgery (e.g., esophagectomy). An important nontraumatic cause is malignancy, especially lymphoma. Congenital chylothorax arises from thoracic duct malformation, and repair of congenital diaphragmatic defects may cause chylothoraces. Lymphangioleiomyomatosis and nonsurgical trauma rarely produce chylothoraces. Chylothorax is idiopathic in 15% of the reported cases. CT scanning should be performed to exclude lymphoma (and other potential causes) in patients without a history of trauma.

Management of chylothorax aims to optimize nutrition, relieve symptoms, and close the thoracic duct defect. Malnourishment secondary to chyle loss can be disabling. Total parenteral nutrition, or a low-fat diet with medium-chain fatty acids, should be adopted to reduce chyle flow. If the patient is symptomatic with dyspnea, fluid can be removed by

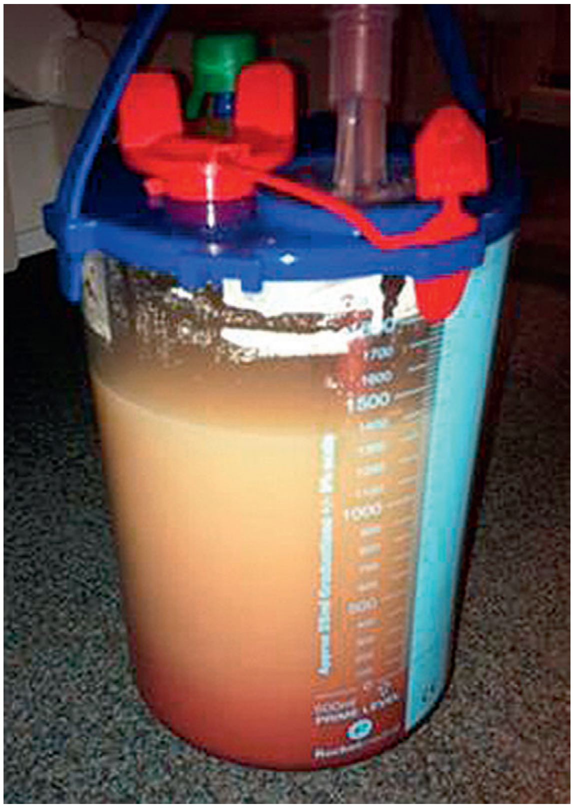

Figure 69-13 Typical appearance of chylothorax drainage.

thoracentesis or chest tube drainage. Pleuroperitoneal shunts have been recommended in the absence of coexisting chyloascites. Pleurodesis has been attempted in refractory cases. With traumatic chylothorax, the defect frequently closes spontaneously. Use of octreotide, a somatostatin analogue, also has been reported, mainly in pediatric-based case series, to enhance thoracic duct closure. Percutaneous thoracic duct embolization performed under radiologic guidance can be attempted before consideration of surgical thoracic duct ligation by VATS or thoracotomy. This approach initially was described in 1998 and offers a minimally invasive treatment strategy for those patients who are unable to tolerate surgical intervention. Catheterization of the thoracic duct is a prerequisite for its use, and anatomic obstruction of the cisterna chyli or retroperitoneal lymphatic chain obviates its use. In patients with underlying lymphoma, radiotherapy or systemic chemotherapy may control the chylothorax.

Pseudochylothorax

Pseudochylothorax, or cholesterol pleurisy, is most commonly associated with tuberculous pleurisy and rheumatoid pleuritis. The pleural fluid has a very high cholesterol content and no chylomicrons. Demonstration of cholesterol crystals is diagnostic. Pseudochylothorax was conventionally thought to result from the accumulation of cholesterol and lecithin-globulin complexes within long-standing pleural effusions enveloped by thickened fibrotic pleura. Recent evidence, however, suggests that such chronicity and pleural fibrosis are not prerequisite in pseudochylothorax from rheumatologic causes. Specific treatment for the condition is seldom indicated. Dyspnea is more likely to be a result of the pleural fibrosis and is seldom relieved by thoracentesis. Respiratory insufficiency, infection, and bronchopleural or pleurocutaneous fistulas are rare complications.

ASBESTOS-RELATED PLEURAL DISEASES

Asbestos fibers have a predisposition to localize to the pleura. Injury to the pleura can result in mesothelioma (see Chapter 70), as well as a range of benign pleural diseases—namely, pleural plaques, diffuse pleural thickening, benign asbestos–related pleural effusions, and round atelectasis.

Circumscribed pleural thickening—pleural plaques—are seen in up to 50% of asbestos-exposed subjects. Plaques occur in the parietal pleura and are of no physiologic consequence. Benign asbestos-related effusions typically are small and unilateral. Their occurrence is dose-dependent on asbestos exposure, with a shorter latency period (within 2 decades of asbestos exposure) than for other asbestos-related pleural disease. The effusion is an exudate, often blood-stained, and may precede the development of diffuse pleural thickening. The diagnosis depends on exclusion of other causes. Prolonged observation is required to exclude mesothelioma. Round atelectasis represents invagination of the visceral pleura and can be diagnosed radiologically by the "comet tail" sign on CT scan. In the absence of classic radiographic features, round atelectasis can mimic lung tumors, and differentiation can be difficult.

Diffuse pleural thickening may occur with asbestos exposure (less than 5%), especially in those with heavy asbestos contact. Significant restrictive lung function changes with resultant dyspnea can occur.

FIBROTHORAX AND PLEURAL THICKENING

Diffuse pleural thickening (fibrothorax) can be secondary to empyema or hemothorax, tuberculous pleurisy, asbestos exposure, collagen vascular disease, and drug-induced pleuritis (e.g., ergot derivatives, such as bromocriptine, pergolide, and methysergide). Pleural fibrosis and thickening also may develop as a result of pleurodesis performed to therapeutically obliterate the pleural space.

Patients with fibrothorax may be asymptomatic or complain of dyspnea. The chest radiograph typically shows concentric pleural thickening, occasionally with evidence of the predisposing cause. Reduction in the size of the hemithorax with an elevated hemidiaphragm suggests chronic fibrosis. Pulmonary function testing usually demonstrates a restrictive pattern. Likewise, long-term survivors of pleurodesis often exhibit radiologic pleural thickening coupled with mild restrictive physiologic changes.

Treatment should be aimed at the underlying cause, with removal of offending agents if possible. Corticosteroids often are administered, and surgical decortication is sometimes attempted; effectiveness of neither approach is established.

OTHER CAUSES OF EXUDATIVE EFFUSIONS

Rarely, exudative effusions may be associated with sarcoidosis, radiotherapy, yellow nail syndrome, familial Mediterranean fever, and amyloidosis.

Approximately 15% of pleural effusions remain undiagnosed despite thorough investigation. Close follow-up may identify those associated with occult malignancy; however, most are benign and resolve spontaneously. It has been postulated, but not proved, that viral infection may be responsible.

CONTROVERSIES AND PITFALLS

Pleural effusions are common. However, pleural effusions often are considered a "side issue" to the underlying systemic or pulmonary disorders causing the effusion. This perspective often results in significant delay in recognition, investigation, and management of the effusion, contributing to morbidity. For example, late recognition of parapneumonic effusions remains commonplace; improved awareness and early intervention would have prevented many cases of empyema.

Advances in imaging will play an increasing role in diagnosis and investigation of pleural disease. High-quality clinical trial data are lacking in pleural disease, and management often is governed by anecdotal experiences.

Several controversies regarding pleural disease management have emerged. The use of some fibrinolytics and other adjunctive therapy (tPA and DNase) in pleural infection has been shown to be beneficial in a randomized controlled trial, but further research is required to define treatment effects. The pros and cons of medical thoracoscopy continue to be debated. The belief that thoracoscopic talc pleurodesis is superior has not been supported by randomized controlled trials. The size of the chest tube and the requisite skills for insertion (i.e., surgical, radiologic, or respiratory medicine) remain controversial.

PNEUMOTHORAX

A pneumothorax exists when air is present within the pleural space and may be classified as spontaneous or traumatic. *Traumatic* pneumothoraces occur as a result of direct or indirect trauma and may be iatrogenic secondary to procedures such as transbronchial or pleural biopsies, thoracentesis, and central venous catheterization.

Spontaneous pneumothoraces are divided into primary and secondary. *Primary* spontaneous pneumothoraces (PSPs) arise in apparently healthy people, whereas *secondary* spontaneous pneumothoraces are associated with underlying pulmonary disease, most commonly chronic obstructive pulmonary disease (COPD). Differentiation between these categories is important, because management and prognosis differ for the two groups (Box 69-4).

Box 69-4 Causes of Pneumothorax

Spontaneous
Primary (most common in young men)
Secondary
  Chronic obstructive pulmonary disease (COPD)
  Asthma
  Cystic fibrosis
  Congenital cysts and bullae
  Pleural malignancy
  Interstitial lung disease
  Bacterial pneumonia
  Pneumocystis jirovecii pneumonia
  Tuberculosis
  Whooping cough
  Langerhans cell histiocytosis (LCH)
  Tuberous sclerosis
  Lymphangioleiomyomatosis (LAM)
  Marfan syndrome
  Esophageal rupture

Traumatic
Penetrating chest wounds
Chest compression injury
  Including external cardiac massage
Iatrogenic
  Pleural aspiration
  Chest tube insertion
  Intercostal nerve block
  Percutaneous lung biopsy
  Radiofrequency ablation of lung lesion
  Transbronchial lung biopsy
  Transbronchial needle aspiration
  Central venous cannulation
  Pacemaker insertion
  Positive-pressure ventilation

PRIMARY SPONTANEOUS PNEUMOTHORAX

Primary pneumothorax usually occurs in young male smokers between 20 and 40 years of age. The reported incidence is 18 to 28 per 100,000 for men and 1.2 to 6.0 per 100,000 for women (male-to-female ratio of 5:1). Cigarette smoking is a major risk factor, increasing the lifetime risk of pneumothorax in healthy males from 0.1% in nonsmokers up to 12% in smokers. The risk is dose-related, with relative risk seven times higher in light smokers (1 to 12 cigarettes/day), 21 times higher in moderate smokers, and 102 times higher in those smoking more than 22 cigarettes daily. This trend is less marked in women. The chronic effects of marijuana smoking and its association with bullous lung disease are now recognized as an independent risk factor for pneumothorax.

Mortality rates for primary pneumothorax are extremely low.

PATHOPHYSIOLOGY

Pneumothorax is attributed to the rupture of subpleural blebs and bullae, which represent so-called early emphysematous-like changes (ELCs). Such changes are demonstrated in the lung apices in most patients with primary pneumothorax despite the absence of underlying clinical disease. Pulmonary blebs are air-filled spaces between the lung parenchyma and the visceral pleura, visible in more than 75% of patients undergoing thoracoscopic treatment for primary pneumothorax. Patients with primary pneumothoraces also tend to be taller and thinner than control subjects, a characteristic associated with an increased pressure gradient from lung base to apex. This feature creates a greater distending pressure on apical alveoli, thereby increasing the likelihood of rupture. However, ELCs are present in up to 25% of control subjects and are not always predictive of pneumothorax.

Fluorescein-enhanced autofluorescence thoracoscopy techniques have identified areas of increased visceral pleural porosity in the absence of other visible abnormality. It is hypothesized that air leakage from these areas may be integral to the formation of primary pneumothoraces. Smoking-induced distal airway inflammation, disturbance of collateral ventilation, congenital anatomic, and morphometric abnormalities may contribute to these changes.

A tendency toward primary pneumothorax is rarely inherited, and the Birt-Hogg-Dube syndrome (inherited as an autosomal dominant trait that has been localized to chromosomal region 17p11.2) is associated with primary pneumothorax, benign skin tumors, and renal tumors. Patients with Marfan syndrome and homocystinuria also have an increased incidence of pneumothorax.

CLINICAL PRESENTATION

Primary pneumothorax may be asymptomatic, but sudden-onset pleuritic chest pain localized to the affected side of the pneumothorax or dyspnea is the most common symptom.

On examination, a hyperresonant percussion note, absence of tactile fremitus, and reduced breath sounds on the affected side may be evident. Tracheal deviation away from the affected side is seen with large, or tension, pneumothoraces. Signs of hemodynamic compromise (hypotension, severe tachycardia, and cyanosis) suggest a tension pneumothorax. Hamman's sign, an audible clicking sound synchronous with the heart sounds, can be heard with a left-sided pneumothorax, and subcutaneous emphysema may be palpable.

DIAGNOSIS

Chest radiographs usually confirm the diagnosis. Expiratory films are no more sensitive than standard films, although lateral decubitus views facilitate the detection of tiny pneumothoraces. In up to 50% of cases, a small ipsilateral pleural effusion also is seen, and mediastinal displacement away from the pneumothorax, subcutaneous emphysema, or pneumomediastinum may coexist. Thoracic ultrasound imaging has a role in ruling out pneumothorax, particularly after interventional procedures, but is hampered by false-positive findings with bullous lung disease (e.g., COPD) or previous pleurodesis and is unable to accurately predict pneumothorax size. CT scanning is rarely necessary acutely in primary pneumothorax and is recommended only if concern exists regarding underlying complex cystic disease or to differentiate between a bulla and pneumothorax.

The "gold standard" for pneumothorax size assessment is CT scanning, but this modality is not used in routine practice. Pneumothorax size may be estimated using chest radiography and *Light's index*: percent pneumothorax = 100 – [100 × (diameter of deflated lung)^3/(diameter of hemithorax)^3]. The latest British Thoracic Society guidelines advocate measurement of pneumothorax depth at the level of the hilum, but American College of Chest Physicians guidelines suggest apex-to-cupola depth measurements (Figure 69-14). A 2-cm depth is advocated as a sensible cutoff value for intervening in primary pneumothoraces, representing an approximately 50% pneumothorax. For patients with a secondary spontaneous pneumothorax, a 1-cm depth is advocated for intervention.

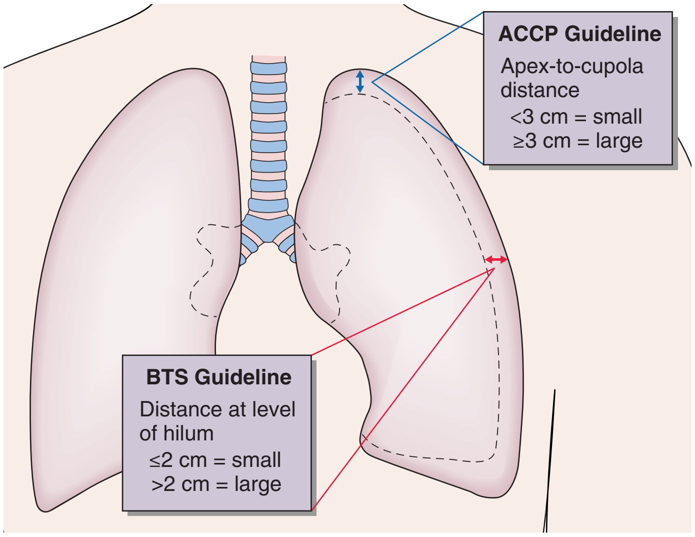

Figure 69-14 Measurement strategies proposed for quantifying pneumothorax size. *ACCP*, American College of Chest Pysicians; *BTS*, British Thoracic Society.

Arterial blood gas measurements may show a reduced PaO_2 and an increase in the alveolar-arterial oxygen gradient, measured as $PO_2(A–a)$.

MANAGEMENT

The management of primary spontaneous pneumothoraces varies widely, with the approach to the patient determined by the clinical presentation. Supplemental high-flow oxygen is advocated by some centers because it can theoretically accelerate pleural air resorption by reducing the partial pressure of nitrogen in the blood. Observation alone may be adequate for patients with small primary pneumothoraces, minimal symptoms, and stable cardiorespiratory status. The rate of spontaneous pleural air resorption is slow (1.25% each 24 hours), and this prolonged course to resolution should be anticipated.

Otherwise, treatment aims to remove air from the pleural space and decrease the risk of recurrence. The former may be achieved by simple aspiration or intercostal tube drainage with or without one-way (e.g., Heimlich) valve insertion. Prevention of recurrence involves removal of risk factors (e.g., smoking cessation) and induction of pleurodesis by means of chemical pleurodesis, thoracoscopy (usually VATS), or rarely, open thoracotomy. The latter two approaches allow identification and resection of abnormal areas (ELC treatment [e.g., bullectomy]) with or without chemical pleurodesis, pleural abrasion, or partial pleurectomy (Figure 69-15).

Simple aspiration is the accepted treatment in patients with large or symptomatic small primary pneumothoraces. This technique succeeds in approximately 60% of patients. If complete reexpansion is not achieved but symptoms are relieved, outpatient follow-up is appropriate. Alternatively, a Heimlich flutter valve (thoracic vent) may be inserted and the patient safely discharged with scheduled outpatient review.

Intercostal tube drainage is indicated if pleural aspiration fails to control symptoms. Small (10 to 14F) drains usually are adequate. Once the lung is reexpanded and the drain ceases bubbling for 24 hours, it should be removed. Suction may aid reexpansion but should not be applied before 48 hours to lessen the risk of reexpansion pulmonary edema (RPE). The risk of RPE increases with the length of time the lung has been collapsed. Clamping of the nonbubbling chest tube before removal is a contentious issue. A slow air leak may become apparent only after the drain has been clamped for several hours, so this maneuver may be of value in avoiding premature removal.

SURGICAL TREATMENT

Surgery is indicated in cases of persistent air leak despite adequate tube drainage. Surgery also is indicated in patients with recurrent ipsilateral or first contralateral pneumothorax, synchronous pneumothoraces, or a spontaneous hemothorax, as well as those with job restrictions (e.g., divers, airline pilots).

Minimally invasive VATS allows stapling of blebs and bullae using an Endostapler, laser ablation, or electrocoagulation. Pleurodesis can be induced mechanically with pleural abrasion or partial pleurectomy or chemically (talc poudrage). Recurrence rates after VATS are less than 5%, and this technique is associated with shorter hospital stays and recovery time than with open surgery. The emergence of fluorescein-enhanced autofluorescence thoracoscopy may help identify parenchymal abnormalities not visible on routine thoracoscopy.

Thoracotomy and transaxillary minithoracotomy are indicated only if VATS is unavailable. Recurrence rates are less than

1%, but potential morbidity is greater than with minimally invasive procedures.

STRATEGIES FOR AVOIDING RECURRENCE

The risk of recurrence after a primary spontaneous pneumothorax is approximately 30% (16% to 54%) and is greatest in the first few months. Recurrence rates increase with successive pneumothoraces—50% after one recurrence and up to 80% after a third pneumothorax. The risk of contralateral pneumothorax is approximately 15% after a primary event. The recurrence rate is higher in taller patients, smokers, and those with greater number of subpleural blebs or bullae.

Definitive surgical intervention, accomplished by either VATS or open thoracotomy, achieves recurrence rates superior to those after instillation of a pleurodesing agent (usually sterile talc) through the intercostal tube. However, if the patient is unwilling or too frail to undergo surgery, or if thoracoscopy is unavailable, bedside pleurodesis may be appropriate.

SECONDARY SPONTANEOUS PNEUMOTHORAX

Secondary pneumothoraces occur in patients with underlying lung disease, often with impaired respiratory reserve. The reported incidence is similar to that of primary spontaneous pneumothorax, with highest rates (60 cases per 100,000 population per year) in men older than 75 years of age. COPD is a comorbid condition in 60% of patients. *Pneumocystis jirovecii* (i.e., “*Pneumocystis* pneumonia” [PCP]) infection in patients with acquired immunodeficiency syndrome (AIDS) is another risk factor. Other associated conditions are outlined in Box 69-4.

Secondary pneumothorax carries a mortality rate of up to 10%, often indicative of the severity of the underlying lung disease.

CLINICAL PRESENTATION

The symptoms of secondary pneumothorax are similar but often are more severe than those associated with primary pneumothorax. Clinical deterioration may be rapid and of a magnitude disproportionate to the pneumothorax size.

On physical examination, contralateral differences may not be readily apparent in patients with hyperexpanded lungs secondary to COPD.

DIAGNOSIS

Chest radiography confirms the diagnosis in most cases. In patients with underlying lung disease, however, the typical radiographic appearance of a pneumothorax may be altered, and careful distinction between hyperlucent bullae and a pneumothorax must be made. If the diagnosis is in doubt, additional imaging (e.g., CT) should be used before aspiration is attempted.

Arterial blood gas analysis commonly shows hypoxia proportional to the extent of underlying disease and pneumothorax size. Acute hypercapnic respiratory failure may be seen and should resolve after treatment.

MANAGEMENT

Secondary pneumothoraces must be recognized and treated promptly. The evacuation of even a small pneumothorax can rapidly relieve symptoms in these patients.

The initial treatment for most patients is intercostal tube insertion. Observation alone is inappropriate, except in asymptomatic patients with tiny apical pneumothoraces, and aspiration should be considered only in minimally symptomatic patients with small pneumothoraces.

Because air leaks are more common in secondary pneumothoraces, the lung remains unexpanded in approximately 20% of the cases at 7 days. The median time to lung expansion is 5 days, compared with 1 day for primary pneumothoraces. Suction can be applied if the lung fails to spontaneously reinflate.

SURGICAL TREATMENT

Early surgical intervention is recommended in patients with a persistent air leak or failure of reexpansion after 72 hours. VATS is well tolerated by most patients and may supersede more invasive techniques (e.g., open thoracotomy). In persons at high risk for adverse anesthetic events, chemical pleurodesis with delivery of the sclerosing agent through the intercostal tube can be performed.

In other patients in whom tube thoracostomy has failed and surgery is not appropriate, a Heimlich flutter valve can be inserted. Success rates of up to 100% have been reported in patients with advanced AIDS and PCP (see later discussion).

STRATEGIES FOR AVOIDING RECURRENCE

Attempts to prevent recurrence should be considered for all patients after their first secondary pneumothorax, because approximately 45% of this group will have further recurrent episodes.

Open thoracotomy with pleurectomy has the lowest recurrence rate after pneumothorax (approximately 1%), but the less invasive VATS with pleural abrasion or surgical talc pleurodesis usually is preferred and has a recurrence rate of approximately 5%. Many patients, however, will not be suitable candidates for surgical intervention, and chemical pleurodesis performed through a chest tube may be appropriate.

The effect of pleurodesing agents on future lung transplantation must be considered in selected patients. Although not an absolute contraindication, pleurodesis makes transplantation technically more difficult, thereby prolonging the period of donor organ ischemia. Excessive bleeding also is more common. Close liaison with the local transplantation unit is advised for all possible future transplant candidates in whom pleurodesis is contemplated (see Chapter 75).

DISCHARGE AND FOLLOW-UP EVALUATION

Any patient discharged with a residual pneumothorax should have a repeat chest radiograph to ensure complete lung reexpansion. Those who have undergone successful aspiration can be discharged unless an underlying lung abnormality is suspected, when CT imaging may be indicated.

All patients should be cautioned against air travel until 1 week after full lung reexpansion demonstrated on chest radiograph. The risk of recurrence is greatest within the first year, and those with secondary pneumothoraces may wish to avoid flying for a longer period.

Diving should be permanently avoided unless a definitive surgical procedure such as surgical pleurectomy has been performed. Smoking cessation should be strongly encouraged.

SPECIAL SITUATIONS

IATROGENIC PNEUMOTHORAX

Iatrogenic pneumothorax probably is more common than primary and secondary forms of pneumothorax combined, and the incidence is escalating with increasing use of invasive procedures (e.g., transbronchial or percutaneous lung biopsy). Transthoracic needle aspiration accounts for up to one quarter of all cases, especially if the patient has underlying emphysema or aerated lung is traversed during biopsy or radiofrequency ablation of tumor.

A high index of clinical suspicion should be maintained in any patient who becomes breathless after a procedure associated with risk for pneumothorax, and in patients being mechanically ventilated who deteriorate suddenly. The diagnosis is confirmed on a chest radiograph.

In most cases, the patient can be managed with observation and oxygen administration alone. If the patient is more than minimally symptomatic, however, simple aspiration is recommended. Chest tube drainage should be initiated should symptoms persist or if the patient has underlying lung disease. Surgical intervention occasionally is required if the air leak persists (e.g., for longer than 72 hours). Pneumothorax recurrence is not an issue in persons with iatrogenic pneumothoraces unless concomitant lung disease is present.

TENSION PNEUMOTHORAX

Tension pneumothorax constitutes a medical emergency. A defect in the visceral pleural surface acts as a one-way valve, so that air is drawn into the pleural space with inspiration and is unable to leave on expiration. The resulting increase in intrapleural pressure impairs venous return, leading to reduced cardiac output and hypoxemia. Clinically, acute respiratory distress with sweating, tachycardia and hypotension develops; if this disorder goes unrecognized, a pulseless electrical activity (PEA) cardiac arrest may ensue. Tension pneumothorax should be considered when sudden decline occurs in mechanically ventilated patients.

If tension pneumothorax is suspected, treatment should be instituted without delay; awaiting confirmation on the chest radiograph increases the risk of death. The patient should receive high-flow oxygen, and a 16- to 18-gauge cannula should be inserted into the second intercostal space in the midclavicular line. An audible hiss may be noted after insertion. Once enough air has been aspirated to relieve symptoms, an intercostal chest drain should be placed, and a chest radiograph then obtained.

SURGICAL/SUBCUTANEOUS EMPHYSEMA

Surgical emphysema arises as air, under pressure from the pleural space, dissects through the subcutaneous tissue (**Figure 69-16**).

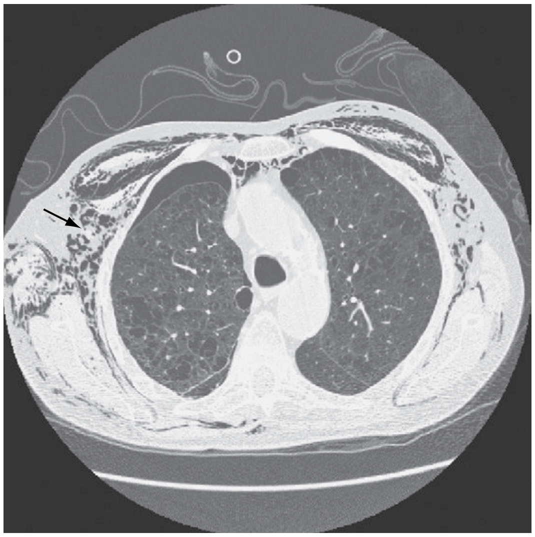

Figure 69-16 Subcutaneous emphysema (*arrow*) complicating secondary pneumothorax related to chronic obstructive pulmonary disease (COPD).

This complication may result from misplacement of a drain with the air holes positioned outside the pleural cavity, from blockage of the drain, or in the presence of a large air leak.

In most cases, no action is required for the surgical emphysema; correction of the drainage problem to prevent further air accumulation in the subcutaneous tissue is adequate. Rarely, acute airway obstruction may develop with secondary respiratory compromise. Tracheostomy may be required to secure the airway and high-flow oxygen applied (in the absence of any contraindications). Skin incision decompression and subcutaneous drains also have been tried.

CATAMENIAL PNEUMOTHORAX

Catamenial pneumothoraces typically develop within 48 hours of onset of menstrual flow and tend to recur. The diagnosis should be considered in women who are seen with recurrent pneumothoraces, with or without a history of endometriosis. This diagnosis often is overlooked, and patients have, on average, five episodes before diagnosis.

The pathogenesis is not fully understood. Most pneumothoraces occur on the right, supporting the hypothesis that air originates from abdominal organs (e.g., endometriotic involvement of the gastrointestinal or uterine tract) and passes into the pleural cavity through diaphragmatic defects. Pleural or diaphragmatic endometriosis may be involved in creating such defects. Alternatively, air may have originated from endometriosis in the lungs.

Treatment of endometriosis with hormonal manipulation is effective in some patients. Alternative therapeutic options include thoracoscopy for pleurodesis and closure of diaphragmatic defects.

PNEUMOTHORAX AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Pneumothorax occurs in 2% to 5% of patients with AIDS. PCP induces a subpleural necrotizing alveolitis responsible for the high frequency and recurrence rate in these patients. Approximately 5% of persons who use prophylactic nebulized pentamidine also will experience spontaneous pneumothoraces.

Management of AIDS-related pneumothorax is notoriously difficult. Early tube thoracostomy and talc pleurodesis or referral for VATS should be considered. Ambulatory drainage with Heimlich valves has been successfully used.

PNEUMOTHORAX IN CYSTIC LUNG DISEASES

Cystic Fibrosis

Development of pneumothorax in patients with cystic fibrosis (CF) carries an important prognostic implication; median survival after pneumothorax is 30 months. The pneumothorax itself is not the cause of demise but is a surrogate marker of end-stage lung disease, because patients with a forced expiratory volume in 1 second (FEV_1) of less than 30% predicted are most at risk. Occurrence of pneumothorax usually is unrelated to acute respiratory illness. Adherence to the standard guidelines for management is recommended, however, with concomitant antibiotic use to avoid secondary infection. Pleurodesis to prevent recurrence of pneumothorax is important, because recurrence rates are approximately 50%. Early liaison with the transplantation team is appropriate if surgical input is required.

Pulmonary Langerhans Cell Histiocytosis

Spontaneous pneumothorax may be the presenting feature in up to 25% of patients with Langerhans cell histiocytosis (LCH). Treatment options are those discussed previously for pneumothorax, together with management of the underlying LCH (see Chapter 54).

Lymphangioleiomyomatosis

In addition to chylothorax, patients with lymphangioleiomyomatosis (LAM) are at risk for development of pneumothorax. This complication is common in this population (affecting up to 80%) and may be the presenting feature of the underlying LAM. Recurrent pneumothoraces occur in two thirds of patients, and early definitive intervention is recommended to reduce recurrence rates. Pleurodesis may increase the rate of perioperative bleeding (occurring as a result of resultant adhesions) but does not preclude successful future lung transplantation (see Chapter 54).

CONTROVERSIES AND PITFALLS

The cause of pneumothorax remains poorly understood. Only a small proportion of subjects with CT evidence of blebs or cystic lung changes actually develop a pneumothorax. Advances in diagnostic technologies (e.g., fluorescein-enhanced autofluorescence thoracoscopy [FEAT]) may shed light on the pathogenesis of pneumothorax. Early evidence casts doubt on whether air leaks truly originate from blebs (as per conventional teachings) or from other abnormal pleural areas identified on FEAT (possibly representing pleura with increased porosity, which may contribute to air leakage). Data from the use of one-way endobronchial valves for persistent air leak demonstrate that a mean of 2.9 valves are required to stop or improve the leak in more than 90% of patients; such data strongly suggest that collateral ventilation between different lung segments and subsegments is important. The concept that pneumothorax can be attributed to one pulmonary (sub) segment and its associated bronchus is overly simplistic.

The optimal management of pneumothoraces remains debatable. The use of suction early in the course of treatment and clamping of the intercostal drain remain controversial topics. Management strategies that use less invasive drainage (e.g., simple aspiration) and early ambulatory drainage with one-way valves are increasingly being adopted by some clinicians. On the other hand, widespread acceptance of minimally invasive thoracoscopic surgery may prompt earlier referral in the future and even first-line thoracoscopic treatment. The best management of pneumothoraces in potential future lung transplant candidates is unclear, and further investigation is needed on optimal timing for air travel in patients with recent pneumothorax.

Section 13
DISORDERS OF THE PLEURA AND MEDIASTINUM

Chapter 70
Malignant Pleural Mesothelioma

Tarek Meniawy • Bruce W.S. Robinson

Malignant mesothelioma is a neoplasm arising from the mesothelial surface of the pleura, peritoneum, pericardium, and tunica vaginalis, with the majority of cases arising in the pleura. Malignant pleural mesothelioma (MPM) has progressively increased in incidence worldwide, associated with increasing exposure to asbestos in the post–World War II era. The disease is preceded by a long latency period, often more than 30 years. Incidence of MPM is expected to peak in the Western world in the next one or two decades because of regulation of asbestos use and increasing public awareness of its health risks since the 1970s and 1980s. However, MPM will continue to increase in many developing countries, where asbestos remains widely used.

EPIDEMIOLOGY

A relationship between asbestos exposure and development of mesothelioma was first reported in 1960 by Wagner et al., who described a cohort of 33 patients who developed diffuse malignant mesothelioma after exposure to asbestos in the North Western Cape Province of South Africa. Subsequent reports in many countries indicated a rising incidence of mesothelioma. Also, it was reported that the risk of developing mesothelioma was dose dependent, with the rate increasing significantly with time from first exposure, duration of exposure, and cumulative exposure. MPM is often preceded by a prolonged latency period of 20 to 60 years.

A review by Price and Ware of mesothelioma time trends in the United States based on the April 2008 release of the Surveillance Epidemiology and End Result (SEER) data estimated that 2400 cases were diagnosed in 2008, with asbestos likely to be the cause in 58%. They also reported a possible shift in the peak incidence in the United States from a peak between 2000 and 2004 to a peak between 2005 and 2010, and that after 2042, mesothelioma cases diagnosed in the United States will be predominantly caused by "background mesothelioma" rather than asbestos-related MPM.

A similar trend is evident in other Western countries and regions, where several decades of rising incidence of MPM have peaked or will peak in the next 20 to 30 years. The regulatory laws introduced progressively since the 1970s restricted asbestos use in various industries, eventually resulting in a total ban in most developed countries and regions. Again, in many Third World and developing countries where asbestos is still widely used and mesothelioma may also be underreported, incidence will increase for decades.

Mesothelioma has also been linked to nonoccupational and environmental exposure to asbestos in multiple epidemiologic studies. Malignant mesothelioma caused by both occupational and nonoccupational asbestos exposure was notably studied in Wittenoom, Western Australia. In areas of Turkey, exposure to *tremolite* asbestos, commonly used in the white stucco covering walls in houses has been linked to mesothelioma. Another fibrous mineral, *erionite*, has been associated with MPM in three "cancer villages" in the Cappadocia region of Turkey; later reports suggested that this occurs most often in families with genetic predisposition to mineral fiber carcinogenesis.

The *simian virus* 40 (SV40) was proposed to act as a "cocarcinogen" with crocidolite asbestos, resulting in malignant transformation, and was shown to induce mesothelioma in hamsters. The same group subsequently demonstrated SV40 viruslike DNA sequences in patients with malignant mesothelioma. The role of SV40 in mesothelioma remains controversial.

Radiation therapy has been linked to MPM in patients followed up after treatment for non-Hodgkin lymphoma. *Carbon nanotubes,* which are lightweight, strong cylindrical molecules, are increasingly being incorporated into modern manufacturing processes, including electronics, sports equipment, and protective clothing. Initially believed to pose no health risks, they appear to have some similarities to asbestos and were demonstrated to cause mesothelioma when injected into mice. A role for nanotubules in human mesothelioma has not been established, although any long incubation period would make it unlikely that cases would have yet been seen.

Although *smoking* and asbestos exposure can multiplicatively increase the risk of developing lung cancer, smoking has not been demonstrated to have an independent association with mesothelioma.

PATHOGENESIS

Asbestos is a term used to describe a group of mineral fibers of two major types: serpentine and amphibole. *Chrysotile* is the most common *serpentine* asbestos used commercially and has long, curly and pliable fibers. The *amphiboles,* which are short, straight, and stiff, include *crocidolite* (blue asbestos) and *amosite.* Noncommercial amphiboles include tremolite, which is present in the soil in Turkey, Greece, Afghanistan and other regions.

Controversy surrounds the role of different types of asbestos fibers and the exposure threshold for malignant transformation, particularly the role of chrysotile asbestos. The general consensus is that the amphibole crocidolite is the most carcinogenic form of asbestos, and that asbestos fibers of greater length and smaller diameter (high length/width ratio) are more carcinogenic, possibly because they can penetrate farther into the pleura.

Asbestos can affect the pleura by four main processes. First, asbestos fibers can penetrate deeply into the lung and irritate the pleura, eventually leading to either scarring (plaques) or malignant transformation. The fibers may also pierce the mitotic spindle and result in chromosomal damage, with loss of chromosome 22 being the most common gross change. Third, DNA can be damaged through the formation of iron-catalyzed free radicals. Fourth, asbestos can increase expression of proto-oncogenes through phosphorylation of mitogen-activated protein (MAPK) and extracellular signal-regulated kinases (ERK) 1 and 2. In addition, the following six alterations in cell physiology that can dictate malignant growth, as described by Hanahan and Weinberg, also appear to be present in mesothelioma:

1. Mesothelioma cells have increased or *dysregulated growth* through both production of and response to various growth factors.
2. Mesothelioma cells express telomerase and therefore avoid telomere shortening (i.e., become "*immortalized*").
3. Tumor suppressor genes such as p16 and p14, which are important in the Rb and p53 pathways, are absent in mesothelioma, allowing the tumor to *avoid antigrowth signals*.
4. Tumor cells *evade apoptosis* through increased activity of the antiapoptosis molecule Bcl-2.
5. *Increased angiogenesis* occurs through production of angiogenic factors such as vascular endothelial growth factor.
6. Malignant mesothelioma exists in a collagenous environment, and *matrix interactions* and regulation of this environment likely are related to tumor growth.

The SV40 virus may play a role in the pathogenesis of MPM and is a subject of ongoing study to clarify its role. The SV40 large T antigen (SV40Tag) can inhibit p53 and Rb tumor suppressor genes. SV40 infection is also involved in activation of various pathways, including Wnt, ERK, PI3K/Akt, and Notch-1 pathways, and has a co-carcinogenic effect with asbestos.

PATHOLOGY

Gross Pathology

Diffuse MPM is characterized by multiple pleural nodules that progress along the pleural surface, leading to circumferential thickening that encases the lung in a rindlike manner. It may also appear as a single area or multiple areas of thickening or tumor masses. Local invasion of the chest wall, lung, or mediastinum can also occur. *Localized* MPM is a much less common entity involving circumscribed masses that do not show the same diffuse pattern of spread along the pleura.

Histology

A definitive diagnosis of MPM is best made with an adequate biopsy in the context of compatible clinical findings. This often represents a diagnostic challenge because of the relatively low frequency of cases outside large tertiary care centers, the often limited amount of tissue available for examination, the heterogeneity of histologic appearance of the same tumor within a patient, and the differential diagnoses of benign pleural disease or other metastatic malignancies. With the increasing availability of immunohistochemical stains, molecular studies, and electron microscopy, diagnostic accuracy has improved. It remains critical for diagnosis to correlate the pathologic findings with the clinicoradiologic features to reach a definitive diagnosis.

The three main subtypes of diffuse MPM are epithelial (epithelioid), sarcomatous (sarcomatoid), and biphasic mesothelioma, with various histologic patterns within each subtype.

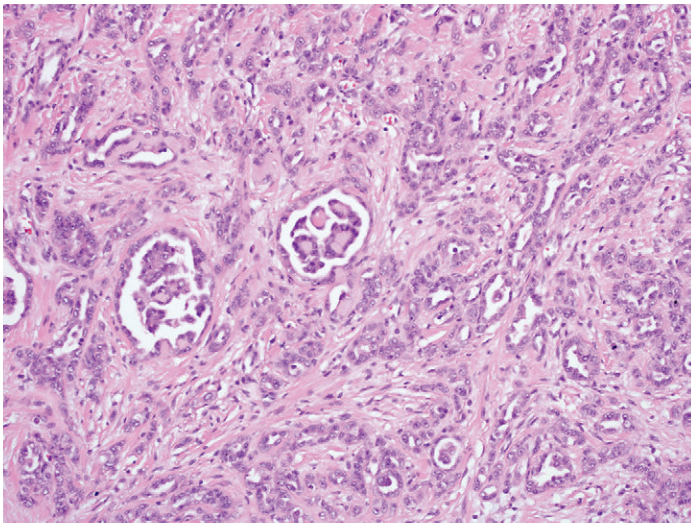

Figure 70-1 Epithelioid mesothelioma with tubulopapillary growth pattern (hematoxylin-eosin stain [H&E]; ×200).

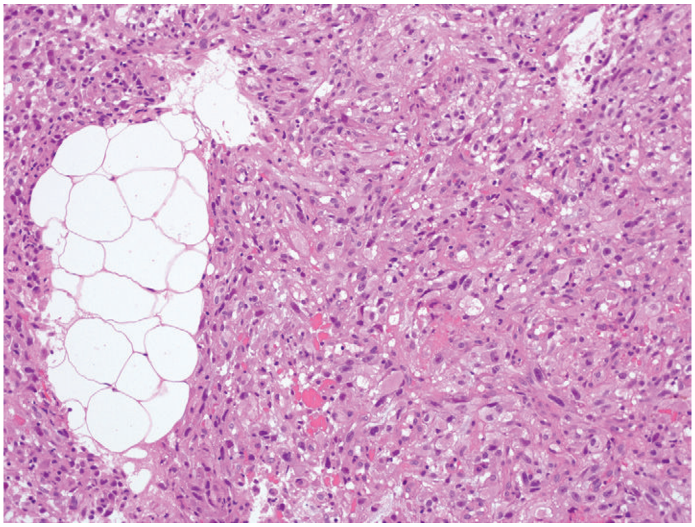

Figure 70-2 Sarcomatoid mesothelioma surrounding chest wall fat (H&E; ×200).

Epithelial Subtype

Epithelioid MPMs are the most common subtype and can be further characterized to a number of patterns. The tubulopapillary pattern contains a mixture of tubules and papillary structures (Figure 70-1). Adenomatoid and acinar patterns contain glandlike structures that should be differentiated from adenocarcinomas of other origin (e.g., lung). The solid, well-differentiated pattern has "nests" or sheets of cells that may resemble reactive mesothelium. Differentiating features from *reactive mesothelial hyperplasia* include stromal invasion, presence of necrosis and expansile nodules, as well as immunohistochemical staining patterns. Other types include solid, poorly differentiated, clear cell, and others.

Sarcomatous Subtype

Sarcomatoid MPMs usually show spindle cells, often have more necrosis and atypical cells than epithelioid patterns, may contain anaplastic or giant cells, and include the lymphohistiocytoid and desmoplastic patterns (Figure 70-2). The desmoplastic pattern contains dense areas of collagen with small amounts of tumor cells, without significant atypia, and can be difficult to differentiate from nonmalignant pleural conditions such as fibrosing pleuritis; differentiating features include stromal invasion and disorganized growth with uneven thickness.

Biphasic (Mixed) Subtype

Biphasic or mixed MPMs contain elements from both epithelioid and sarcomatoid subtypes, with at least 10% of each required for a diagnosis of "biphasic diffuse MPM."

Cytology

Given that many patients with MPM present with a pleural effusion, cytopathologists and surgical pathologists debate the utility of pleural effusion cytology in the diagnosis. Cell blocks of cytologic samples from pleural effusions used for immunohistochemistry panels similar to those for biopsy specimens have led to more confident diagnosis of MPM when compatible clinicoradiologic findings are present. Morphologic findings alone are not adequate because malignant and reactive epithelial cells share features that make definitive diagnosis difficult. In addition, malignant cells are not usually present in pleural effusions from sarcomatoid effusions, which may contain only reactive mesothelial cells.

The American Thoracic Society, International Mesothelioma Interest Group (IMIG), and European Respiratory Society/European Society of Thoracic Surgeons task force guidelines all acknowledge a role for cytology in the diagnosis of MPM, but favor analysis of a tissue specimen for a definitive diagnosis. In centers with substantial experience in mesothelioma, however, a diagnosis by cytopathology alone is considered possible when combined with immunocytochemical staining.

Immunohisto/Cytochemistry

Immunohistochemistry (IHC) is an important diagnostic tool in MPM. The exact makeup of panels depends on the histologic subtype and type of tumor being considered in the differential diagnosis, as well as the available antibodies. The IMIG consensus statement recommends the use of positive and negative markers with sensitivity or specificity greater than 80% and positivity that considers stain localization and percentage staining (>10%), as follows:

- Reactive mesothelial hyperplasia and epithelioid MPM may be differentiated by a combination of morphologic features and IHC staining; *desmin* is often positive in reactive hyperplasia, and *epithelial membrane antigen* (EMA) and *p53* may be positive in epithelial MPM.
- Malignant mesothelioma (MM) versus metastatic malignancy (often adenocarcinoma) is a common differential diagnosis. Adenocarcinomas often contain intracellular mucin on periodic acid–Schiff stain after digestion, which is only rarely seen in MM. As a general approach, initial IHC workup may include two mesothelial markers and two markers for the malignancy being considered, as well as *pancytokeratin*, which is positive in almost all MPMs, except less common sarcomatoid variants. If the tumor is keratin negative, panels for other cancers (e.g., melanoma, lymphoma) would be considered.
- Positive mesothelioma markers include calretinin, keratin 5/6, WT-1 protein, and podoplanin (D2-40). Markers that favor lung adenocarcinoma include Ber-EP4, which is positive in 95% to 100% of cases, compared to less than 20% of mesotheliomas. Carcinoembryonic antigen (CEA), TTF-1, MOC-31, BG8, B72.3, and CD15 are often positive in adenocarcinoma but only in up to 10% of mesotheliomas.
- When lung squamous cell carcinoma (SCC) is suspected, keratin 5/6 is not useful, being positive in both mesothelioma and lung SCC, but p63 is useful as it is expressed in almost all SCCs and in 7% of mesotheliomas. MOC-31, BG8, and Ber-EP4 are also often positive in lung SCC.
- If initial IHC panel results are conflicting, these can be expanded to include additional markers.

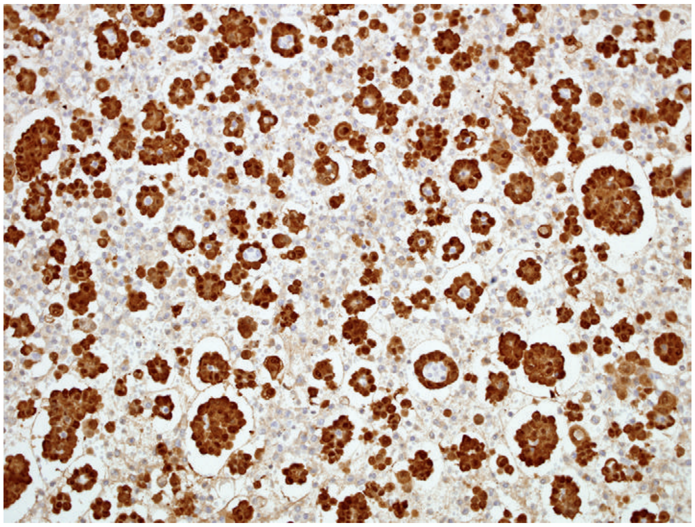

Figure 70-3 Pleural effusion cytology: calretinin stain in malignant mesothelioma (calretinin-immunoperoxidase; ×200).

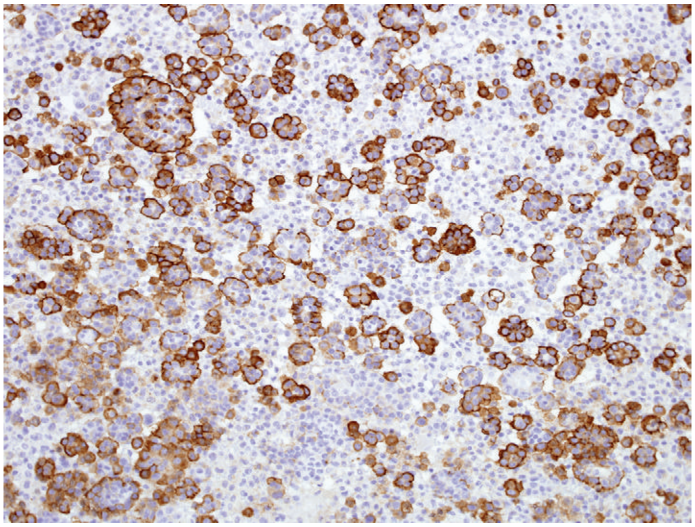

Figure 70-4 Pleural effusion cytology: epithelial membrane antigen (EMA) stain in malignant mesothelioma (EMA-immunoperoxidase; ×200).

Immunocytochemistry (ICC) follows the same logic: determine if the cells are of mesothelial origin (e.g., using calretinin; Figure 70-3), then determine if they are malignant (e.g., using EMA to determine if there is a dense peripheral staining pattern; Figure 70-4). It is essential that the correct anti-EMA antibody is used because some give better results than others, partly contributing to dissent on the role of ICC in diagnosing mesothelioma.

Electron Microscopy

The ultrastructural features of MPM are well described, and electron microscopy (EM) was once the "gold standard" for diagnosing MPM. However, the availability of increasing numbers of suitable antibodies for IHC has largely replaced routine EM, which requires significant expense and expertise and therefore is not widely available outside major centers. MPM diagnosis usually requires a combination of EM features rather than individual features, such as long, thin microvilli, prominent desmosomes, and presence of basal lamina. EM remains useful in well-differentiated to moderately differentiated epithelioid MPM when IHC results are conflicting, especially where differentiation from adenocarcinoma is required.

CLINICAL PRESENTATION

Malignant pleural mesothelioma is most common in men, with age at presentation typically 50 to 70. Presentation at a younger age may also occur in the patient with significant childhood exposure. The insidious onset of symptoms often leads to a delay of 2 to 3 months from initial symptoms to diagnosis, and 25% of patients may not present for evaluation for 6 months or more. Most patients present with a pleural effusion, and the majority develop an effusion at some stage of disease. The most common symptoms at presentation are breathlessness (40%-70%) and chest pain (60%). Constitutional symptoms such as weight loss and fatigue often are not present at diagnosis but develop with progression of disease. Patients may also present with symptoms from local spread causing superior vena cava syndrome, spinal cord compression, pericardial involvement, or chest wall invasion.

The only abnormal physical finding is often of a unilateral pleural effusion, which more frequently (60%) affects the right hemithorax. Tumor spread through the pleural cavity may result in signs of a “fixed” hemithorax. There may be palpable chest wall masses or signs caused by local or distant spread.

There are no specific laboratory features for MPM. Nonspecific findings include anemia, hypergammaglobulinemia, eosinophilia, and thrombocytosis, which is present in 60% to 90% of patients. Pulmonary function tests may show a restrictive pattern, which may result from lung encasement or chest wall involvement.

Distant metastases were present postmortem in 54% to 82% of mesothelioma patients in one large series. However, distant metastases usually are not evident clinically at diagnosis and are not the cause of death. Intracranial metastases may be present infrequently (3%). With the increasing use of positron emission tomography (PET) for diagnostic workup, 5% to 25% of patients may show extrathoracic disease at diagnosis. Miliary spread of mesothelioma has also been described.

DIAGNOSIS

The initial diagnostic workup for patients presenting with an unexplained pleural effusion or pleural thickening is pleural aspiration. Pleural biopsy by sampling an area of the affected pleura with an Abrams needle can be performed, but this blind biopsy is painful and has a yield of only 39% to 60%. In a randomized study, computed tomography (CT) guidance had significantly higher sensitivity than blind biopsy (87% vs. 47%).

Thoracoscopy may be indicated if pleural aspiration is nondiagnostic and for patients who develop recurrent pleural effusions. It has the advantage of a higher sensitivity (98%) and the ability to estimate the extent of involvement of the mediastinum, chest wall and diaphragm, and providing adequate tissue for histologic classification in patients being considered for surgery. If a medical or video-assisted thoracoscopy is not possible, an open biopsy may be necessary. The development of chest wall masses from malignant seeding of biopsy tract sites after thoracocentesis or biopsy is an uncommon complication and may be prevented by radiotherapy to the site after instrumentation, although recent work questions this.

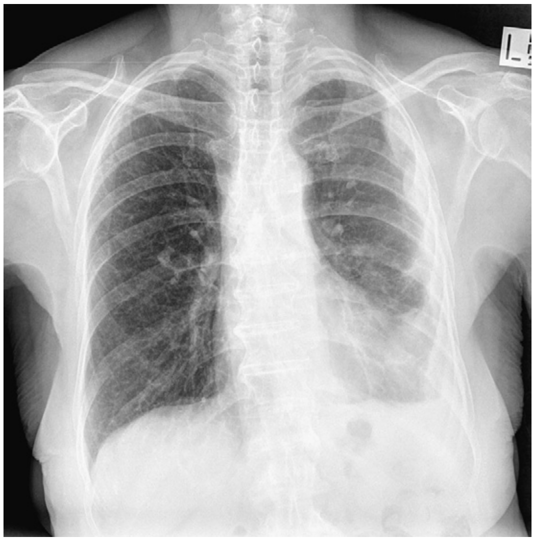

Figure 70-5 Plain chest radiograph of patient with left-sided malignant pleural mesothelioma, demonstrating diffuse pleural thickening and pleural effusion.

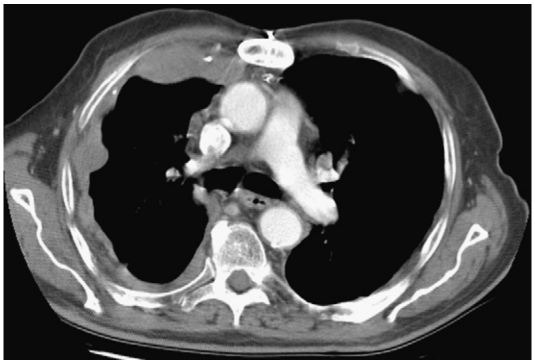

Figure 70-6 Computed tomography scan of patient with right-sided pleural mesothelioma, with diffuse pleural thickening and large focal nodules.

Imaging

The most common finding with MPM on plain chest radiography is a unilateral pleural effusion (Figure 70-5). Pleural thickening may also be seen, or in more advanced cases, an encircling “rind” of tumor or lobulated pleural masses. Signs of asbestos exposure, such as pleural plaques, may be present but are not a precursor to mesothelioma.

Computed tomography of the chest may show only a pleural effusion (74%). Pleural-based masses with or without thickening of the interlobular septa are not seen in most patients at presentation but develop later in the disease course (Figure 70-6). Lower lobe collapse may result from pleural encasement, pulmonary nodules (60%), or lymphadenopathy affecting the hilar and mediastinal lymph nodes.

Magnetic resonance imaging (MRI), although not commonly used, may be useful in determining the extent of tumor spread, particularly diaphragmatic invasion or assessment of suspected spinal cord metastases.

Positron emission tomography with fluorodeoxyglucose (FDG-PET) may be helpful to distinguish MPM from benign

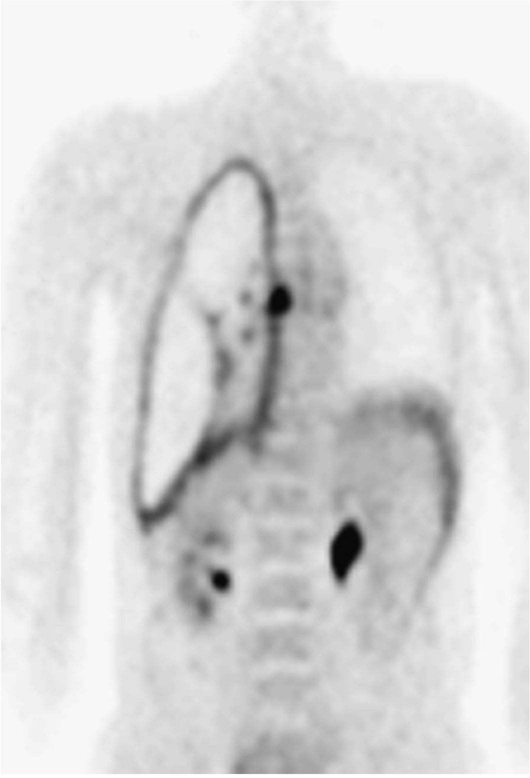

Figure 70-7 Positron emission tomography with fluorodeoxyglucose (PET-FDG) in patient with pleural mesothelioma shows extensive uptake involving right hemithorax with local lymph node involvement.

pleural disease (Figure 70-7). PET may also be useful in excluding extrathoracic disease in patients being considered for surgery, but is less accurate for defining locoregional spread to mediastinal lymph nodes. Integrated PET-CT may be more reliable in defining extent of disease than PET, CT, or MRI alone. Changes in PET results may predict response to chemotherapy.

Biomarkers

Two biomarkers, *soluble mesothelin-related peptides* (SMRPs) and osteopontin, have been extensively investigated as potential diagnostic or treatment monitoring markers. *Mesothelin* is a 40-kDa glycoprotein expressed on the surface of mesothelial cells and is overexpressed in mesothelioma. Serum SMRPs were increased in 84% of 44 patients with MPM, and in only three (2%) of 160 control patients. SMRPs measured in pleural effusions have also been investigated. In 192 patients presenting to respiratory clinics, elevated SMRP levels in effusions had a sensitivity of 67% and specificity of 98% for a diagnosis of mesothelioma, often several months before a definitive diagnosis was eventually made (Figure 70-8). Their utility has been validated, and SMRPs are now widely available. Of note, the terms *mesothelin* and *SMRP* are often used interchangeably in the literature.

Osteopontin is a glycoprotein that is overexpressed in several cancers. In a report comparing osteopontin levels in MPM patients and in asbestos-exposed patients, a high level of osteopontin had a sensitivity of 77.6% and specificity of 85.5% for mesothelioma, suggesting that it may be useful for distinguishing these two groups. However, osteopontin lacks specificity in other patients with pleural disease compared with SMRPs and thus is not recommended.

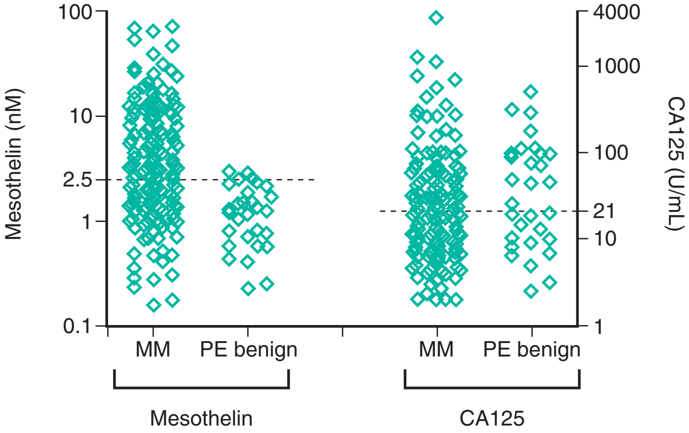

Figure 70-8 Serum mesothelin and cancer antigen 125 *(CA125)* levels in 117 patients with malignant mesothelioma *(MM)* and 30 patients with benign pleural effusions *(PE)* demonstrating similar sensitivity but different specificity levels. At diagnosis, serum mesothelin was elevated in 48% of patients with MM and 3% of patients with benign PE, whereas serum CA125 was elevated in 42% of MM but also in 53% of benign PE.

STAGING

The current staging system of tumor (T), node (N), metastasis (M) is used by both the International Union against Cancer (UICC) and the American Joint Committee on Cancer (AJCC) and was adopted from the staging system proposed by IMIG in 1995. The AJCC TNM staging system for mesothelioma was published in 2010 (Table 70-1). A limitation of staging is that accurate staging, particularly of the T stage, can be determined only by surgical exploration, although initial staging with CT or PET-CT remains valuable.

PROGNOSIS

The median survival of patients with malignant mesothelioma receiving best available treatment is 12 months, or as short as 4 months in patients receiving supportive care alone. The most useful clinical prognostic scoring systems are those derived by the Cancer and Leukaemia Group B (CALGB) and the European Organisation for Research and Treatment of Cancer (EORTC), both validated in subsequent studies. The CALGB index used Cox survival models and regression trees to examine the effects of pretreatment prognostic factors on the survival of 337 patients treated in seven Phase II CALGB clinical trials. Multivariate Cox analysis showed increasing age over 75, pleural involvement, elevated LDH, poor performance status, chest pain, thrombocytosis, and nonepithelial histology to predict a poor prognosis, and six prognostic groups were identified based on these factors. The EORTC identified prognostic factors in 204 patients enrolled in five Phase II trials and reported that a poor performance status, high white blood cell count, male gender, sarcomatous histology, and a probable/possible histologic diagnosis were independent factors of poor prognosis. Patients were classified into a good-prognosis group, with a 40% 1-year survival, and a poor-prognosis group, with a 12% 1-year survival.

An elevated neutrophil/lymphocyte ratio (NLR) at baseline was reported to be an independent prognostic factor in a group of 173 patients undergoing systemic therapy, and normalization of NLR after one cycle of treatment was a predictor of improved survival on subgroup analysis.

Table 70-1 American Joint Committee on Cancer 2010 TNM Staging for Mesothelioma

***Primary Tumor* (T)**			
TX	Primary tumor cannot be assessed.		
T0	No evidence of primary tumor		
T1	Tumor limited to ipsilateral parietal pleura with or without mediastinal pleura and with or without diaphragmatic pleural involvement		
T1a	No involvement of visceral pleura		
T1b	Tumor also involving visceral pleura		
T2	Tumor involving each ipsilateral pleural surface (parietal, mediastinal, diaphragmatic, visceral), with at least one of the following: Involvement of diaphragmatic muscle Extension of tumor from visceral pleura into underlying pulmonary parenchyma		
T3	Locally advanced but potentially resectable tumor Tumor involving all ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, visceral), with at least one of the following: Involvement of endothoracic fascia Extension into mediastinal fat Solitary, completely resectable focus of tumor extending into soft tissues of chest wall Nontransmural involvement of pericardium		
T4	Locally advanced, technically unresectable tumor Tumor involving all ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, visceral) with at least one of the following: Diffuse extension or multifocal masses of tumor in chest wall, with or without associated rib destruction Direct transdiaphragmatic extension of tumor to peritoneum Direct extension of tumor to contralateral pleura Direct extension of tumor to mediastinal organs Direct extension of tumor into the spine Tumor extending through to internal surface of pericardium, with or without a pericardial effusion or tumor involving myocardium		
***Regional Lymph Nodes* (N)**			
NX	Regional lymph nodes cannot be assessed.		
N0	No regional lymph node metastases		
N1	Metastases in ipsilateral bronchopulmonary or hilar lymph nodes		
N2	Metastases in subcarinal or ipsilateral mediastinal lymph nodes, including ipsilateral internal mammary and peridiaphragmatic nodes		
N3	Metastases in contralateral mediastinal, contralateral internal mammary, and ipsilateral or contralateral supraclavicular lymph nodes		
***Distant metastasis* (M)**			
M0	No distant metastasis		
MI	Distant metastasis present		
Anatomic Stage/Prognostic Groups			
Stage I	T1	N0	M0
Stage IA	T1a	N0	M0
Stage IB	T1b	N0	M0
Stage II	T2	N0	M0
Stage III	T1, T2	N1	M0
	T1, T2	N2	M0
	T3	N0, N1, N2	M0
Stage IV	T4	Any N	M0
	Any T	N3	M0
	Any T	Any N	M1

From American Joint Committee on Cancer, 2010.

The standardized uptake value (SUV) on PET correlated with survival. Multivariate analysis of 65 patients with MPM demonstrated a longer survival for the group with low-SUV tumors than those with high-SUV lesions.

Gene expression array technology has been investigated as a potential prognostication tool. A molecular predictive test that stratifies patients with good or poor outcomes using relative expression of four genes has been prospectively validated in a group of patients undergoing surgery. Patients with good prognosis had a median survival of 16.8 months, versus 9.5 months for those with poor prognosis. There are no validated tests at present for patients not receiving therapy or for those receiving chemotherapy.

MANAGEMENT

The prognosis of the patient with MPM remains poor, with almost all patients eventually succumbing to their illness. Management options include surgery, chemotherapy, and radiotherapy, with the goal of palliating symptoms or prolongation of survival.

Surgery

The role of surgery in MPM, particularly radical surgery, remains controversial. No randomized controlled trials (RCTs) support radical surgery, and there is considerable difficulty in conducting such trials. Four types of surgery are performed as treatment for mesothelioma: *extrapleural pneumonectomy* (EPP), *pleurectomy/decortication* (P/D), limited pleurectomy, and thoracoscopy with pleurodesis. EPP usually involves an en bloc resection of the lung, pleura, pericardium, and diaphragm, whereas P/D involves resection of the parietal and visceral pleurae, pericardium, and diaphragm but spares the lung.

Although medium-term to long-term survival after multimodality treatment with EPP and radio/chemotherapy has been reported in surgical series from specialized centers, the optimal procedure for patients undergoing resection for early MPM is controversial. Most studies have included exclusively either P/D or EPP as part of multimodality therapy, and selection bias plays a major role in determining the type of surgery, or indeed whether surgery is considered. A retrospective case-control study comparing EPP and P/D for pathologic N2 disease in 57 patients suggested that P/D did not compromise survival for these patients. Retrospectively analyzing outcomes for 663 patients undergoing EPP or P/D at the Memorial Sloan-Kettering Cancer Center, National Cancer Institute, and Karamanos Cancer Institute, Flores et al. reported that patients who underwent P/D had better survival than those undergoing EPP, but acknowledged that the reasons were multifactorial and subject to selection bias, suggesting that therapy should be tailored for individual patients. Operative mortality was 4% for P/D and 7% for EPP.

An important unanswered question is whether radical surgery offers any advantage over nonsurgical therapies. Some patients survived long term after surgery, but these patients might have had slow-growing disease and may have had similar survival without surgery. In most surgical series, the survival benefit could not be specifically attributed to the procedure rather than other components of multimodality therapy. Furthermore, survival analysis for patients who were well enough postoperatively to receive radiotherapy and chemotherapy introduces further selection bias. The Mesothelioma and Radical Surgery (MARS) trial, a feasibility study randomizing patients to trimodality therapy (EPP, chemotherapy, radical radiotherapy) or identical chemotherapy, followed by appropriate nonsurgical treatment, established that randomization to surgical or nonsurgical resection was feasible, but the study was not powered to address effectiveness and may not provide a definitive answer on the role for surgery. The MARS investigators have proposed a further trial of surgery (MARS-2), that may evaluate P/D as well as respiratory function and quality of life.

For the small proportion of patients presenting with early, potentially resectable MPM, thorough staging with PET-CT, bilateral thoracoscopy, mediastinoscopy, and laparoscopy may avoid major surgery in patients with disease outside the ipsilateral hemithorax. These patients should be counseled on the risks and benefits of radical surgery, including the limitations of available evidence, and referred to a thoracic surgeon with experience in radical surgery, if appropriate.

Limited pleurectomy or thoracoscopy with talc pleurodesis are palliative procedures that can be effective for control of pleural effusions (discussed later).

Radiotherapy

Radiation therapy can be beneficial in mesothelioma but is limited by the need to treat large areas of the hemithorax. Also, the dose is limited by sensitivity of the heart, liver, lung, esophagus, and spinal cord. External beam radiation therapy (EBRT) can palliate symptoms such as painful chest wall metastases in some patients. Radiotherapy has also been used following instrumentation to prevent tumor seeding (discussed above).

Adjuvant radiotherapy is used as a component of multimodality therapy following radical surgery, but there are no RCTs. Intensity-modulated radiation therapy (IMRT) may have reduced toxicity compared with EBRT while improving local control after EPP, but fatal pneumonitis was reported in one smaller series.

Chemotherapy

Systemic platinum-based chemotherapy is the only treatment for the patient with MPM that has a demonstrated survival benefit from RCTs. In 2003 a landmark study of 226 patients with advanced MPM randomized to *cisplatin* and *pemetrexed* combined or cisplatin alone. Median survival improved from 9.3 months for the cisplatin arm to 12.1 months for the cisplatin/pemetrexed group ($p = 0.02$). Radiologic objective response rate, time to progression, and quality of life and symptom distress measures also improved in the two-drug group. In another RCT, the addition of *raltitrexed* to cisplatin showed a similar overall survival benefit: 11.4 months for cisplatin/raltitrexed versus 8.8 months for cisplatin.

Neither of these trials compared chemotherapy to best supportive care, an issue investigated in the MS01study, which compared "active symptoms control" (ASC) to *vinorelbine* or to mitomycin, vinblastine, and cisplatin (MVP). Because of slow accrual, the two chemotherapy arms were combined, and no overall survival benefit was demonstrated over ASC. However, the two chemotherapy arms were significantly different, with vinorelbine demonstrating a 2-month survival advantage that approached significance, suggesting that MVP was not an active regimen in this setting.

The cisplatin/pemetrexed combination has become the standard first-line therapy for patients with MPM in many centers, but *carboplatin* is often substituted for cisplatin for simpler administration and less toxicity, with Phase II evidence of activity and response rates of 20% to 30%. An expanded-access program demonstrated a lower response rate for carboplatin/pemetrexed but similar 1-year survival and time to progression as with cisplatin/pemetrexed. Other regimens with a good response rate include cisplatin and *gemcitabine*, with good response rates in Phase II trials, but this has not been tested in Phase III trials.

There is no second-line therapy with a proven survival advantage that can be considered the standard of care in the MPM patient. It may be reasonable to use pemetrexed in the second-line regimen when not used in first-line therapy, although there is only low-level evidence for this strategy. The timing of initiating chemotherapy (early vs. delayed) in one small randomized study showed an advantage for the early-treatment strategy, but used MVP, not currently considered an active regimen. Other strategies being investigated include the role of maintenance therapy after first-line treatment and the addition of a third cytotoxic agent to initial two-drug chemotherapy.

Targeted Therapies

Several targeted agents have been investigated in mesothelioma, and many more are currently in ongoing trials. A randomized study of cisplatin and gemcitabine with or without the vascular endothelial growth factor (VEGF)–blocking monoclonal antibody (mAb) *bevacizumab* showed disappointing overall efficacy results. Other VEGF–tyrosine kinase (TK) inhibitors have not shown significant activity. Growth factor pathways have also been targeted with selective and multitargeted TK inhibitors, including erlotinib, gefitinib, sorafenib, and sunitinib, but none has a clear role at present in the management of MPM. Other targets and drugs in Phase I and Phase II trials include the proteasome inhibitor *bortezomib* and the mammalian target of rapamycin (mTOR) inhibitor *everolimus*.

Immunotherapy

Mesothelioma appears to be quite sensitive to immunotherapy. MMP expresses self-antigens that include mesothelin and Wilms tumor 1 (WT-1) as well as mutations that represent potential targets for immunotherapies. The recombinant antimesothelin immunotoxin SS1P and the antimesothelin mAb MORAb-009 have shown some activity in Phase I trials in combination with cisplatin and pemetrexed and are the subject of further trials. WT-1 peptide vaccinations, immunogene therapy, systemic and local cytokines, and autologous tumor vaccination are other strategies being investigated.

Response Assessment

The progress of MPM or response to treatment may be assessed by a number of methods. Patients may report an improvement in pain, breathlessness, or functional status. A reduction in size of a chest wall mass or pleural effusion on clinical examination or plain radiography may also indicate a treatment response.

A radiologic response assessment on CT using the Response Evaluation Criteria in Solid Tumors (RECIST) is often required for patients enrolled in clinical trials. However, tumor measurement in mesothelioma is problematic because of the rindlike pattern of growth along the pleural surfaces, which makes bidimensional measurements of discrete tumor masses difficult. A modified version of the RECIST criteria has been developed specifically for mesothelioma and is based on measurement of tumor thickness on multiple levels on CT.

Given its ability to measure tumor metabolic activity rather than size alone, PET scanning has been investigated as a response assessment tool in several cancers. In a prospective study of 20 patients with mesothelioma receiving first-line chemotherapy, the semiquantitative analysis of serial FDG-PET scans performed at baseline and after one cycle of chemotherapy correlated with response to chemotherapy and patient survival. Changes in mesothelin levels are also useful in following progress.

MANAGEMENT OF PLEURAL EFFUSIONS

The management of an initial pleural effusion is thoracocentesis to drain the fluid and initiate the diagnostic workup. Further management of recurrent effusion is guided by rate of reaccumulation, as well as patient symptoms and preferences, and may involve insertion of an indwelling catheter, chemical pleurodesis via catheter or thoracoscopy (most often with talc), or less frequently with partial pleurectomy. Placement of an indwelling (tunneled) catheter is a relatively simple procedure and is the preferred option in many centers because it provides good symptom relief, a low rate of complications, and achieves spontaneous pleurodesis in a significant proportion of patients.

SUPPORTIVE CARE

Pain in patients with MPM may result from involvement of the chest wall or invasion of intercostal nerves or organs. The use of opiates is often helpful, as well as antiinflammatories and agents for management of neuropathic pain, such as pregabalin or valproate sodium. Palliative radiotherapy is also beneficial in some patients. Those with dyspnea may also require opiate analgesia, in addition to addressing any reversible causes such as pleural effusion or anemia.

Psychosocial issues are an important consideration for patients with MPM, who may have feelings of anger or fear compounded by the medicolegal process often associated with this diagnosis.

CONTROVERSIES AND PITFALLS

Patients with MPM often have an insidious onset of symptoms that may lead to a delay in diagnosis. A high index of clinical suspicions and a comprehensive history, including occupational and environmental exposure to asbestos, as well as appropriate investigation may reduce this delay and enable patients to receive potentially beneficial therapies.

Some centers experienced in cytology methods are able to make a definitive diagnosis of MPM on cytologic samples, using specific antibodies, but centers with less experience continue to rely on tissue samples. Definitive diagnosis of MPM may be challenging because of limited available tissue and heterogeneous histologic appearance. Adequate tissue specimens examined by pathologists experienced in diagnosing MPM and using appropriate immunohistochemical panels to differentiate MPM from benign or other malignant disorders, as well as correlation with clinicoradiologic findings, enable a definitive diagnosis in most patients.

Novel biomarkers such as serum or pleural effusion levels of mesothelin may help differentiate benign from malignant causes of pleural effusions that would benefit from further investigation, but these are not in widespread clinical use. Mesothelin has high specificity in blood and pleural fluid and should probably be used more often in the workup of patients suspected of having pleural malignancy.

The role of surgery in the treatment of MPM remains controversial, with improved survival in select patients, who may have had a similar outcome with nonsurgical therapies. For MPM patients considered surgical candidates, comprehensive staging and discussion of available options can avoid a major, potentially futile procedure.

Palliative chemotherapy remains the only treatment modality with a proven survival benefit in patients with advanced MPM able to undergo treatment. Radiotherapy may play a role in palliating symptoms or as a component of multimodality therapy. Because cures are rare, future studies will seek to generate new strategies to circumvent the chemoresistance of MPM.

Malignant pleural mesothelioma research faces many unanswered questions, with limited effective therapies for an aggressive disease with a poor prognosis that will continue to increase in incidence for decades.

CONCLUSION

Controversies surrounding aggressive local therapies will require researchers and mesothelioma patients to accept the critical role for comparative studies and randomization. The many targeted therapies in development should enhance the efficacy of current systemic therapies. Tools and biomarkers for early diagnosis and follow-up continue to be developed, and novel molecular and biologic techniques and therapeutic approaches will ultimately lead to improvements in outcomes. Sequencing the genomes of MPM samples to understand the molecular pathogenesis will uncover new, drug-susceptible targets.

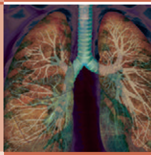
Section 13
DISORDERS OF THE PLEURA AND MEDIASTINUM



Chapter 71
Disorders of the Mediastinum

Diane C. Strollo • Melissa L. Rosado-de-Christenson

The mediastinum is a central space within the thoracic cavity that is bounded by the sternum anteriorly, the pleura and lungs laterally, the vertebral column posteriorly, the thoracic inlet superiorly, and the diaphragm inferiorly. Although the mediastinum is often arbitrarily divided into compartments, true anatomic planes do not exist, and a mediastinal lesion can occupy more than one compartment. Anatomists and surgeons traditionally divide the mediastinum into four compartments: superior, anterior, middle, and posterior.

The best-known imaging division of the mediastinum is based on the location of a mediastinal mass on the lateral chest radiograph. Because the initial imaging evaluation of mediastinal lesions is typically performed with radiography, localization of a mass in a radiographic mediastinal compartment allows the formulation of a focused differential diagnosis.

This chapter divides the mediastinum into anterior, middle-posterior, and paravertebral compartments (Figure 71-1). The *anterior mediastinum* is defined by an imaginary line drawn along the anterior trachea and posterior cardiac border on a lateral chest radiograph. The *paravertebral compartment* is located posterior to an imaginary line drawn to connect the anterior aspects of the thoracic vertebrae. The *middle-posterior mediastinum* is the compartment located between the anterior and paravertebral compartments. Note that the paravertebral regions do not form part of the mediastinum proper.

OVERVIEW OF MEDIASTINAL MASSES

Mediastinal masses are generally described as being predominantly within the anterior, the middle-posterior, or the paravertebral compartment. Cross-sectional imaging allows more accurate localization of mediastinal abnormalities, characterization of the lesions, and visualization of their relationship with and effects on adjacent normal structures.

In adults, approximately 65% of primary mediastinal lesions are located in the anterior mediastinum, 10% in the middle-posterior mediastinum, and 25% in the paravertebral compartment. In contrast, approximately 38% of childhood mediastinal lesions are located in the anterior, 10% in the middle-posterior, and 52% in the paravertebral compartment (Table 71-1).

The most common mediastinal masses are intrathoracic hernia, goiter, neurogenic neoplasms, thymic lesions, lymphomas, cysts, and germ cell neoplasms. Thymic and neurogenic neoplasms and foregut cysts are the most frequent primary lesions in adults, and neurogenic neoplasms, foregut cysts, and lymphoma are the predominant lesions in children. Less frequent mediastinal lesions include lymphangioma, pancreatic pseudocyst, extramedullary hematopoiesis, and meningocele. In addition, lung cancer and mediastinal lymph node metastases may manifest as a mediastinal mass or as extensive mediastinal lymphadenopathy. Non-neoplastic lymphadenopathies, such as sarcoidosis and silicosis, and infectious granulomatous lymphadenopathy may manifest as multiple enlarged mediastinal and hilar lymph nodes and may exhibit calcification.

The nature of mediastinal diseases varies significantly with the patient's age and the clinical presentation. Overall, approximately one third of mediastinal neoplasms are malignant. The mediastinal neoplasms that affect children (40%-50%) are more likely to be malignant than those affecting adults (25%). Most masses (80%-90%) in asymptomatic individuals are benign, whereas approximately 50% of the lesions that produce symptoms are malignant. Conversely, approximately 75% of patients who have malignant neoplasms also have symptoms, compared with less than 50% of patients with benign lesions. Patients with mediastinal masses may experience constitutional symptoms, paraneoplastic syndromes, and symptoms related to compression or invasion of adjacent mediastinal structures. The latter may herald a large, locally invasive or malignant lesion.

The initial evaluation of patients with mediastinal abnormalities includes a detailed history and physical examination to discover specific symptoms and signs of various mediastinal disorders and associated diseases (Table 71-2). Posteroanterior (PA) and lateral chest radiography, computed tomography (CT), and occasionally magnetic resonance imaging (MRI) and fluorine 18 (^{18}F) fluorodeoxyglucose (FDG) positron emission tomography (PET) with CT are used for lesion detection and characterization, usually followed by an invasive procedure for tissue diagnosis. However, some mediastinal lesions have a characteristic radiologic appearance, and biopsy may be unwarranted or contraindicated, as in congenital cysts and vascular lesions, respectively. In addition, laboratory evaluation to include a complete blood count, electrolytes, renal and liver function tests, and serologic tests for various autoantibodies and tumor markers may be useful in the initial evaluation and in posttherapy follow-up.

DISEASES OF ANTERIOR MEDIASTINUM

MEDIASTINAL NEOPLASMS

Thymoma

Thymoma is the most common primary mediastinal neoplasm in adults and the most frequent tumor of the anterior mediastinum. It usually affects adults older than 40 years, with no gender predilection. Approximately 30% of patients with thymoma have thoracic symptoms of cough, dyspnea, and/or chest pain; 40% to 70% have symptoms related to one or more of the parathymic syndromes, typically myasthenia gravis

Table 71-1 Compartmental Classification of Mediastinal Disorders

Abnormality/ Source	Disorder/Abnormality
Anterior Mediastinum	
Disorders of thymus gland	Thymomas: thymic carcinoma, thymic carcinoid, thymolipoma, thymic cyst, thymic hyperplasia Lymphoma: Hodgkin disease, non-Hodgkin lymphoma Germ cell neoplasms *Benign:* Mature teratoma *Malignant:* Seminoma, nonseminomatous germ cell neoplasms
Thyroid	Intrathoracic goiter
Parathyroid	Parathyroid adenoma
Pericardial cysts	
Miscellaneous	Mesenchymal neoplasms (lipoma, liposarcoma, angiosarcoma, leiomyoma) Cystic hygroma (mediastinal lymphangioma)
Middle-Posterior Mediastinum	
Lymph node enlargement	Lymphoma Benign mediastinal lymphadenopathy: Granulomatous disease, infectious (tuberculosis, fungal infections) Noninfectious (sarcoidosis, silicosis) *Miscellaneous causes:* Castleman disease Amyloidosis Metastatic mediastinal lymphadenopathy Lung, renal cell, gastrointestinal, and breast carcinoma
Cysts	Foregut cysts Bronchogenic and enteric cysts
Esophageal disorders	Achalasia, benign tumors, esophageal carcinoma, esophageal diverticulum
Vascular lesions	Aneurysms, hemangioma
Miscellaneous	Herniations, pancreatic pseudocyst
Paravertebral Lesions	
Neurogenic neoplasms	*Peripheral nerve neoplasms:* Schwannoma, neurofibroma Malignant peripheral nerve sheath neoplasm *Sympathetic ganglia neoplasms:* Ganglioneuroma, ganglioneuroblastoma, neuroblastoma *Paraganglionic neoplasms:* Pheochromocytoma, paraganglioma
Spinal	Lateral thoracic meningocele Paraspinal abscess (Pott disease)
Miscellaneous	Extramedullary hematopoiesis Thoracic duct cysts

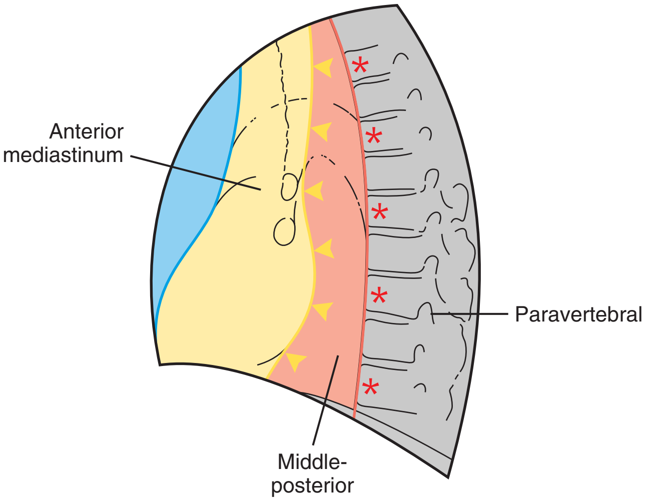


Figure 71-1 Mediastinal compartments on lateral chest radiography. The radiographic anterior mediastinum *(yellow)* is situated anterior to an imaginary line drawn along the anterior tracheal and then continued inferiorly along the posterior heart border. This includes the prevascular space *(blue).* The paravertebral compartment *(gray)* is situated posterior to an imaginary line that joins the anterior thoracic vertebral surfaces. The middle-posterior mediastinum *(pink)* is located between the anterior and the paravertebral compartments. Red asterisks indicate thoracic vertebral bodies.

Table 71-2 Mediastinal Disorders: Constitutional and Paraneoplastic Findings

Diseases	Clinical Findings
Lymphoma	Fever, weight loss, night sweats, pruritus, hypercalcemia
Thymoma	Myasthenia gravis, hypogammaglobulinemia, pure red cell aplasia
Thymic carcinoid secretion	Cushing syndrome, syndrome of inappropriate antidiuretic hormone
Germ cell neoplasm	Gynecomastia, Klinefelter syndrome, hematologic neoplasms
Intrathoracic goiter	Hyper/hypothyroidism
Pheochromocytoma	Hypertension, hypercalcemia, polycythemia, Cushing syndrome
Autonomic ganglia neoplasm	Opsomyoclonus, hypertension, watery diarrhea, Horner syndrome
Sarcoidosis	Hypercalcemia

(MG), but hypogammaglobulinemia, pure red cell aplasia, and nonthymic malignancies may also occur. Some affected patients are asymptomatic and are discovered incidentally because of abnormal chest radiographs. Although the association of thymoma and MG is well recognized, approximately 85% of patients with MG have thymic lymphoid hyperplasia, and only 15% are found to have thymoma. In contrast, 30% to 50% of patients with thymoma may develop MG. Hypogammaglobulinemia and pure red cell aplasia occur in 10% and 5% of patients who have thymoma, respectively. Nonthymic malignancies occur in 12% to 20% of patients with thymoma and include thyroid carcinoma, lung cancer, and lymphoma.

Thymomas manifest on radiography as rounded, well-circumscribed, unilateral, anterior mediastinal masses (Figure 71-2). They are typically located anterior to the aortic root but may be found anywhere from the thoracic inlet to the diaphragm and rarely in the neck. On cross-sectional imaging, thymomas are often homogeneous, soft tissue masses but may exhibit heterogeneity because of cystic change, hemorrhage, or necrosis, especially in large neoplasms. *Drop metastases* to the ipsilateral pleura, pericardium, or upper abdomen through a diaphragmatic hiatus are well documented and represent invasive disease (Figure 71-3). Pleural drop metastases may encase

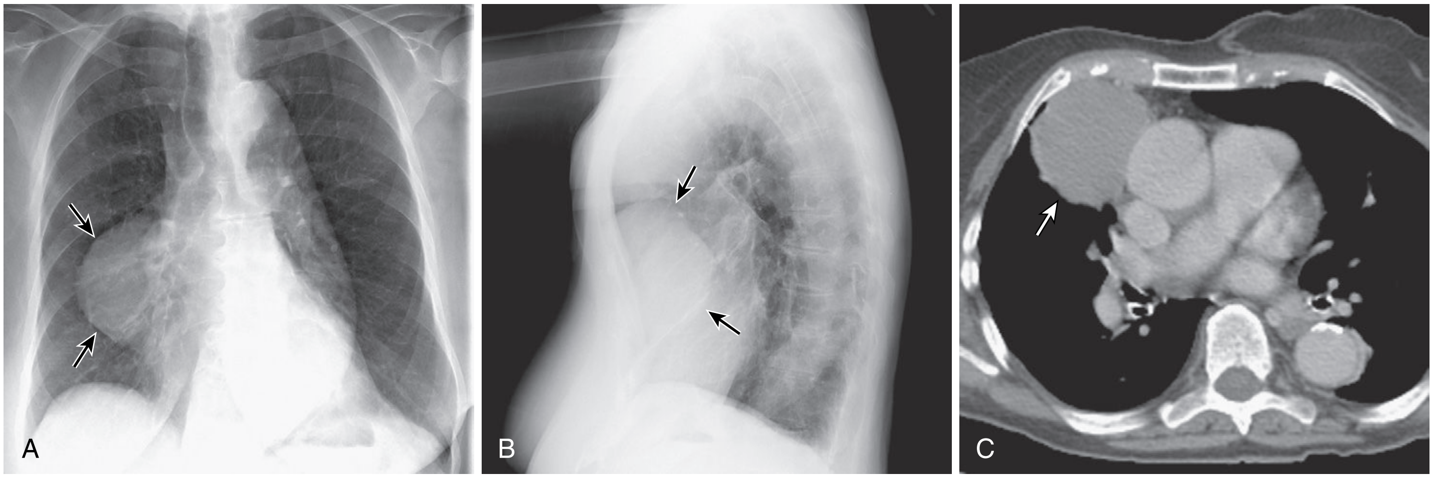

Figure 71-2 Elderly woman with thymoma with microscopic capsular invasion. **A,** Posteroanterior (PA) chest radiograph; **B,** lateral chest radiograph; **C,** contrast-enhanced chest computed tomography (CT) scan (mediastinal window). A 6 × 5 cm discrete homogeneous thymoma *(arrows)* extends inferiorly in the mediastinum without invasion. Thymomas may occur in any location between the thoracic inlet and the diaphragm.

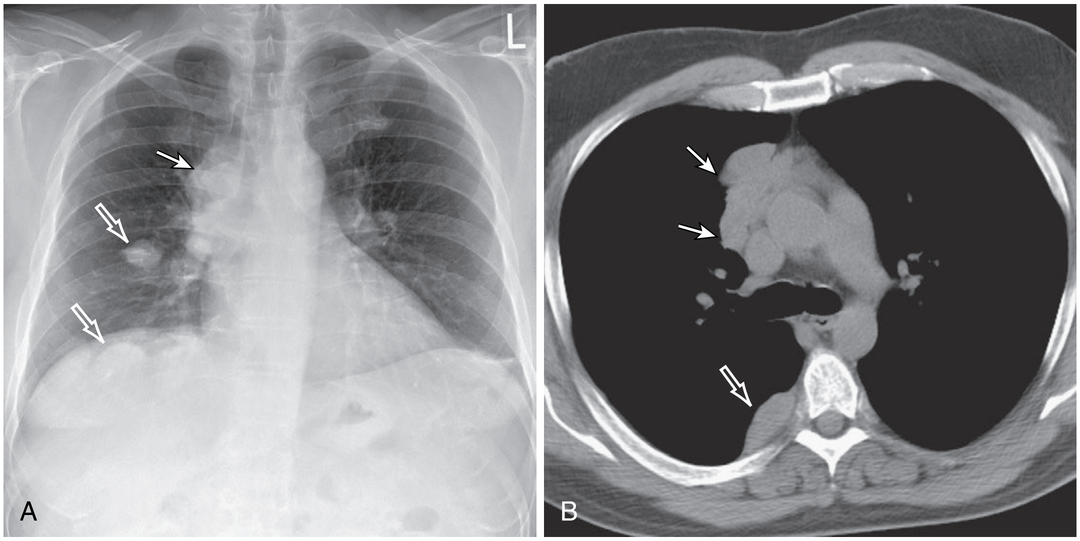

Figure 71-3 Invasive thymoma. **A,** Posteroanterior chest radiograph; **B,** unenhanced chest CT (mediastinal window). Thymoma manifests as a lobular right anterior mediastinal mass *(solid arrows)* with multiple drop metastases to ipsilateral pleura *(open arrows).*

the lung and mimic diffuse malignant mesothelioma, although associated pleural effusion is infrequent. Lymph node and hematogenous metastases are rare. Mediastinal invasion may be detected with CT and may manifest as an irregular tumoral surface, contralateral extension of thymoma across the midline, and obvious invasion of mediastinal fat and structures. Imaging evidence of local invasion must be correlated with microscopic evidence of capsular transgression and tissue invasion, because encapsulated thymomas may produce fibrous adhesions to adjacent structures. MRI is more sensitive than CT in the detection of vascular invasion. When evaluating a thymic mass, PET-CT may be useful for depicting tumoral invasion, differentiating subgroups of thymic epithelial neoplasms, and staging extent of disease. The maximum standard uptake values (SUVs) of thymoma are typically lower than those of thymic carcinoma. Guided needle biopsy, mediastinotomy, mediastinoscopy, and video-assisted thoracoscopy may establish the diagnosis. However, histologic diagnosis before excisional surgery may not be required in classic cases of thymoma.

Thymomas represent neoplastic proliferation of thymic epithelial cells, intermixed with mature lymphocytes. The histologic typing has been complex and challenging. The Revised 2004 World Health Organization (WHO) classification divides thymic epithelial neoplasms into A, B, and C types on the basis of epithelial cell morphology, the ratio of lymphocytes to epithelial cells, and prognosis. Types A and B correlate with the traditional major histologic cell types of thymoma—epithelial, lymphocytic, mixed lymphoepithelial, and spindle cell. Type C refers to thymic carcinoma. The multidisciplinary International Thymic Malignancy Group (ITMG) assesses diagnostic and therapeutic options of thymoma. Anatomic staging is based on the presence or absence of capsular invasion, determined macroscopically during surgery and confirmed microscopically. Thymomas are now considered malignant neoplasms, and all stages have the potential to metastasize. Most thymomas are completely encapsulated; however, approximately 30% are invasive and grow through the capsule into surrounding adipose tissue, pleura, pericardium, great vessels, and/or heart. Encapsulated and invasive thymomas are microscopically identical, and "invasive" is used to denote capsular invasion.

The treatment of choice for encapsulated and invasive thymomas confined to the mediastinum is surgical resection. Postoperative radiation therapy is included in the treatment of invasive thymoma, but the role of preoperative irradiation is controversial. Chemotherapy with cisplatin-based regimens is generally recommended for metastatic or unresectable recurrent disease, with an overall response rate of 50% to 70% in small studies.

The prognosis of patients with thymoma varies with the stage and extent of surgical resection. Patients with completely resected, encapsulated lesions have the best prognosis. Overall 5-year and 10-year survival rates in patients who have encapsulated thymomas are 75% and 63%, respectively, whereas patients with invasive thymoma have survival rates of 50% and 30%, respectively. Delayed recurrence of thymomas may occur, even in patients with completely resected encapsulated lesions, which emphasizes the importance of long-term follow-up.

The role of thymectomy in the treatment of parathymic syndromes is controversial. Thymectomy is more effective in patients with MG in the absence of a thymoma, with a clinical remission rate of approximately 35% and improvement in another 50%. Neurologic improvement is less likely when MG is associated with thymoma. Thymectomy in patients with pure red cell aplasia results in a 40% to 50% remission rate, in contrast to those with hypogammaglobulinemia, who do not benefit from thymic resection.

Thymic Carcinoma

Thymic carcinomas are a heterogeneous group of aggressive epithelial malignancies with a tendency for early local invasion and distant metastases. Men are more often affected (mean age, 46 years). The Revised 2004 WHO classification of *thymic epithelial neoplasms* describes thymic carcinomas as “nonorganotypic” malignancies (type C) that resemble carcinomas of extrathymic origin, such as lung carcinomas. By traditional histopathologic classification, the two most common cell types are squamous cell and lymphoepithelial-like carcinoma. Unlike thymoma, thymic carcinoma has malignant histologic features and typically manifests as a large, poorly defined, infiltrative, anterior mediastinal mass, frequently with regional lymph node and pulmonary metastases, and pleural and/or pericardial effusions (Figure 71-4).

The histologic grade and neoplastic staging determine the therapy and prognosis for the patient with thymic carcinoma. Surgical resection, when feasible, is the preferred treatment. Adjuvant cisplatin-based chemotherapy and concurrent radiotherapy may be used. Response rates are generally poor, with 5-year survival rates of approximately 30%.

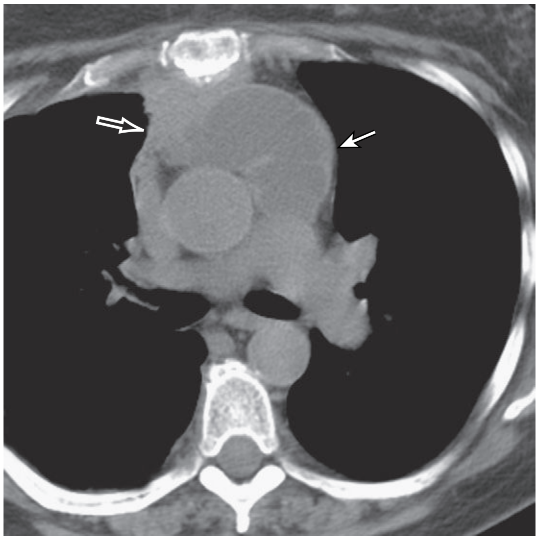

Figure 71-4 Unenhanced chest CT image (mediastinal window) of patient with thymic carcinoma. The heterogeneous left anterior thymic carcinoma extends across the midline of the chest and exhibits multicystic change *(arrow)* and an eccentric mural soft tissue component *(open arrow)*.

Thymic Carcinoid

Thymic carcinoid is a rare, aggressive neuroendocrine neoplasm that typically affects men in the fourth and fifth decades of life. These are large, symptomatic, locally invasive neoplasms with frequent distant metastases. Approximately 35% of affected patients develop endocrine abnormalities caused by ectopic hormone production, most often Cushing syndrome. Multiple endocrine neoplasia syndrome type I (MEN-I) may also occur. However, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and the carcinoid syndrome are rare. Radiologically, thymic carcinoid is a large, lobular, heterogeneous, and usually invasive anterior mediastinal mass indistinguishable from thymic carcinoma or thymoma (Figure 71-5). There may be associated intrathoracic metastatic lymphadenopathy.

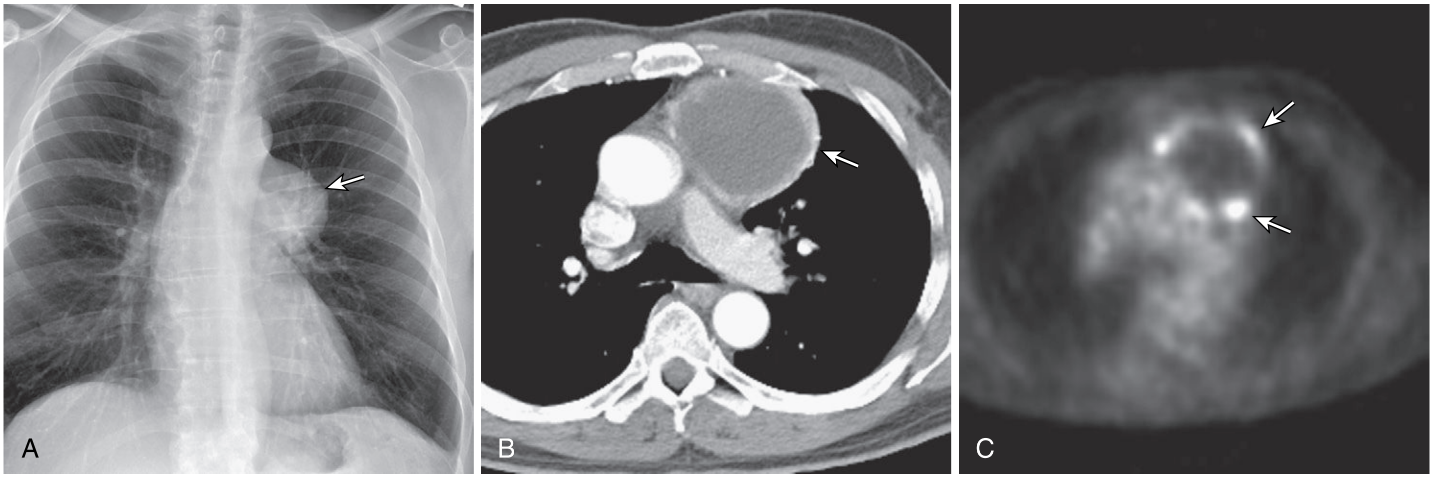

Figure 71-5 Thymic carcinoid. **A,** Posteroanterior chest radiograph; **B,** contrast-enhanced chest CT (mediastinal window). The 6-cm, discrete, rounded left anterior mediastinal thymic carcinoid *(arrow)* exhibits central low attenuation and circumferential mural enhancement. **C,** Fluorodeoxyglucose positron emission tomography (FDG-PET) scan. Multiple FDG-avid foci within the cyst wall *(arrows)* correspond with malignancy.

Surgical resection, when feasible, is the treatment of choice, and response to chemotherapy and radiotherapy is poor.

Mediastinal Lymphoma

Lymphoma represents 10% to 20% of all mediastinal neoplasms in adults. Approximately two thirds of all lymphomas are non-Hodgkin lymphoma (NHL). Mediastinal involvement typically denotes systemic lymphoma but may also represent primary disease. Although both Hodgkin disease (HD) and NHL may affect the mediastinum, mediastinal involvement from systemic lymphoma is much more common in HD than in NHL. *Nodular sclerosis* is the most common subtype of HD to affect the mediastinum. Diffuse, large B-cell lymphoma and lymphoblastic lymphoma represent the most common primary mediastinal subtypes of NHL. Patients affected by NHL have a higher incidence of systemic symptoms and concomitant involvement of extrathoracic and extranodal lymphoid tissue. PET-CT is superior to CT alone in depicting the extent of disease involvement and plays an important role in assessing disease response to therapy and residual viable neoplasm.

Hodgkin Disease

Hodgkin disease is most often seen in adults age 20 to 30 and in those older than 50. Even though the nodular sclerosis subtype is more common in women, HD in general does not exhibit a gender predilection in young patients. Patients who have mediastinal lymphoma tend to be younger. The usual presenting finding is cervical and supraclavicular lymphadenopathy. In less than 25% of patients, HD is limited to the thorax. Approximately one third of patients have systemic symptoms. Patients with mediastinal involvement are generally asymptomatic, although bulky lymphadenopathy may induce symptoms related to mediastinal compression.

Radiologically, most patients with HD have bilateral, asymmetric, mediastinal lymphadenopathy, which frequently involves the prevascular and paratracheal lymph nodes and rarely the posterior mediastinal or juxtacardiac lymph nodes. Nodular sclerosis HD can manifest as a discrete, unilateral anterior mass (Figure 71-6) or bilateral mediastinal mass (Figure 71-7) or as large, lobular, coalescent lymphadenopathy

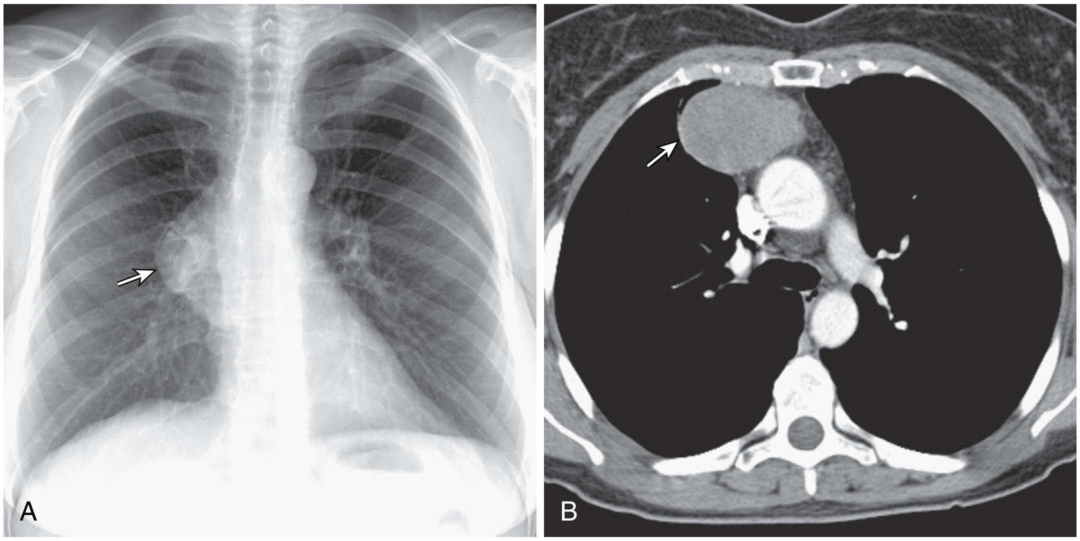

Figure 71-6 Primary mediastinal Hodgkin lymphoma in 45-year-old man. **A,** Posteroanterior chest radiograph; **B,** contrast-enhanced chest CT (mediastinal window). Hodgkin lymphoma manifests as a smooth, homogeneous, right anterior mediastinal mass *(arrow)*, without lymphadenopathy.

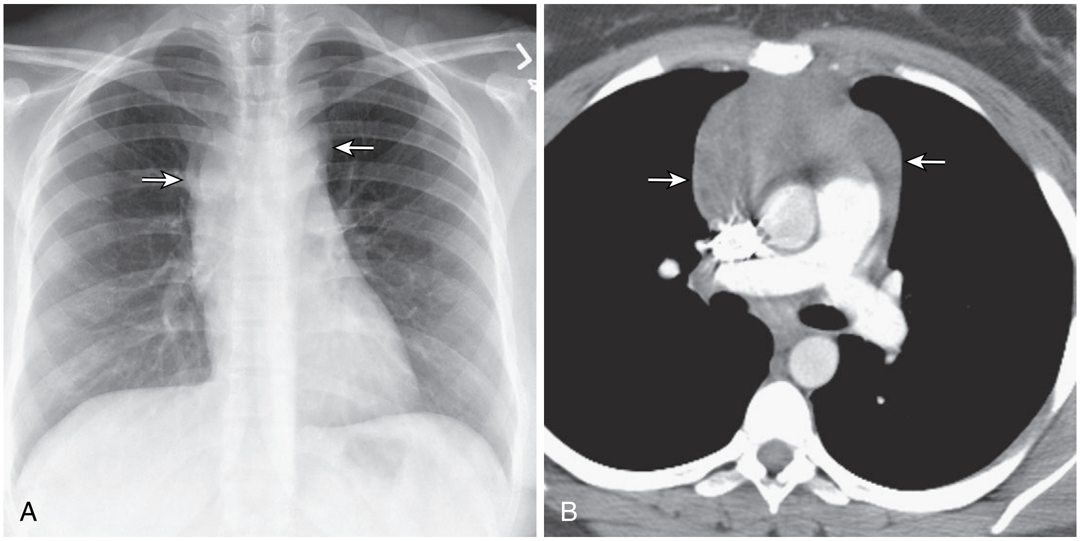

Figure 71-7 Mediastinal mass in Hodgkin disease (HD). **A,** Posteroanterior chest radiograph; **B,** contrast-enhanced chest CT (mediastinal window). Homogeneous central anterior mediastinal mass *(arrows)* extends across the midline bilaterally in woman with HD.

in the anterior mediastinum (Figure 71-8). Invasion, compression, and displacement of mediastinal structures, lung, pleura, and chest wall may occur. Affected lymph nodes usually exhibit homogeneous attenuation but may be heterogeneous because of hemorrhage, necrosis, or cystic change. De novo lymph node calcification rarely occurs but may develop 1 to 5 years after radiation therapy. Direct invasion of the lung occurs in 8% to 14% of untreated patients and is usually associated with hilar lymphadenopathy. The diagnosis is established with either core biopsy or surgical excision of affected palpable lymph nodes or masses found on imaging.

Hodgkin disease spreads by means of contiguous nodal chains and is staged anatomically according to the modified Ann Arbor classification, combined with histologic staging: nodular sclerosis, mixed cellularity, lymphocyte predominant, lymphocyte depletion, and unclassified. Stages IA and IIA HD (asymptomatic disease on same side of diaphragm, without bulky lymphadenopathy) have historically been treated with radiation therapy alone. At this time, limited chemotherapy and limited radiotherapy are being evaluated for early-stage disease. More advanced stages are treated with systemic chemotherapy. Bulky mediastinal lymphoma from HD is treated with chemotherapy followed by radiation therapy. Prognosis depends on the stage of the disease, with cure rates of more than 90% achieved in stage IA and IIA disease; even with diffuse or disseminated involvement of one or more extranodal tissues (stage IV), 50% to 60% of patients can be cured with combination chemotherapy. Recurrences may be cured with salvage chemotherapy.

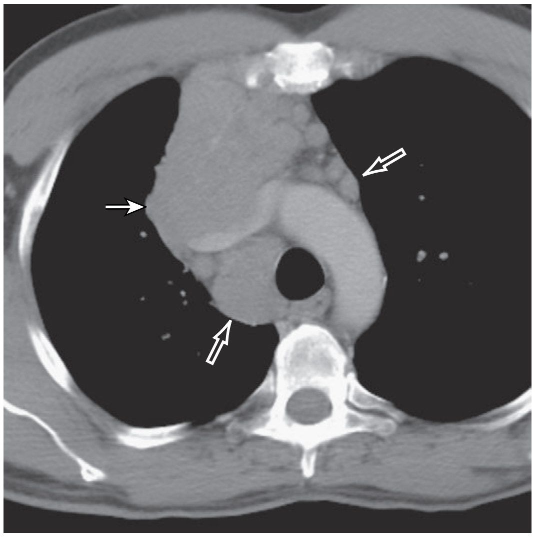

Figure 71-8 Contrast-enhanced chest CT (mediastinal window) of patient with mediastinal Hodgkin disease. A dominant right anterior mediastinal nodal mass *(arrow)* has associated enlarged bilateral contiguous mediastinal nodal groups *(open arrows).*

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma typically affects older patients (compared with those affected by HD) and exhibits a slight male predilection. Diffuse, large B-cell and lymphoblastic lymphomas, the most commonly diagnosed subtype in the mediastinum, occur in younger patients. *Diffuse large B-cell lymphoma* is more common in women, and *lymphoblastic lymphoma* is more common in men and is frequently associated with acute lymphoblastic leukemia (Figure 71-9). Both may produce symptoms related to rapid growth and mediastinal invasion, including the superior vena cava syndrome. In addition, diffuse large B-cell lymphoma and lymphoblastic lymphoma may manifest as a primary mediastinal mass without extrathoracic lymphadenopathy. Most patients with NHL are initially seen with advanced disease and systemic symptoms, and approximately half have intrathoracic lymph node enlargement. Thoracic lymphadenopathy is typically isolated or noncontiguous and tends to occur in unusual sites, such as the paravertebral, juxtacardiac, and retrocrural lymph node groups (Figure 71-10). Anterior mediastinal involvement is less common than in HD, but imaging features are similar to those of HD.

Non-Hodgkin lymphoma is usually systemic on presentation and spreads unpredictably; thus histologic classification has a better prognostic value than anatomic staging. According to the Revised European-American Classification of Lymphoid Neoplasms, NHL can be classified as indolent, aggressive, or highly aggressive. Indolent NHLs are associated with a more favorable histology and a higher likelihood of nodal disease, but a more advanced clinical stage than the aggressive variety, with a propensity to transform into higher-grade lymphomas. Aggressive NHLs have a less favorable histology, with a tendency for extranodal involvement. Although the prognosis is poor if

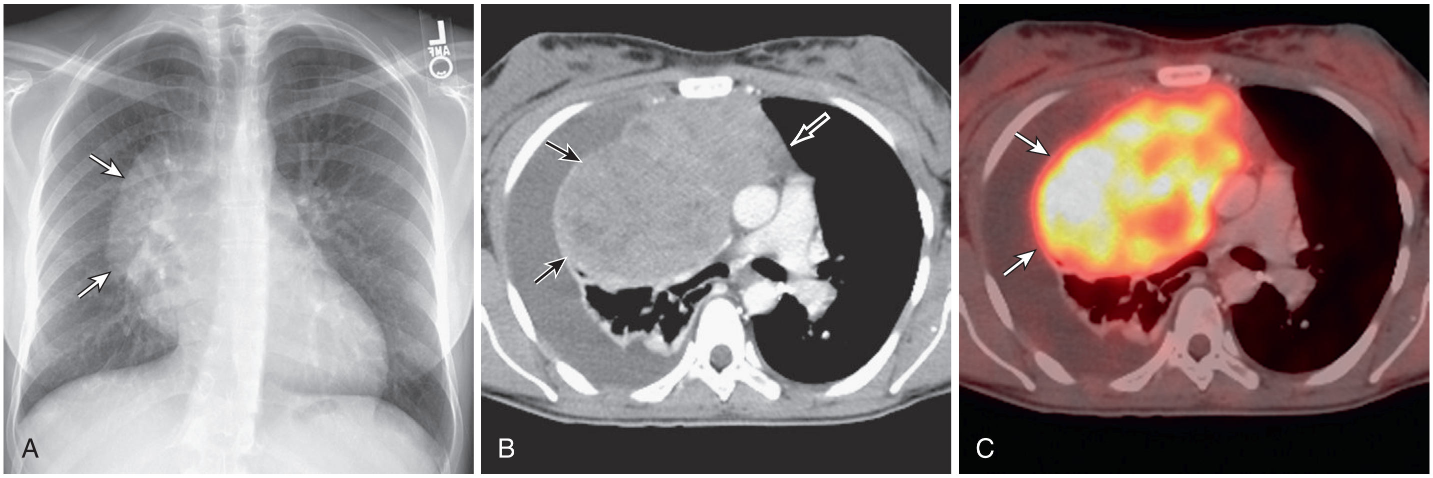

Figure 71-9 Diffuse large B-cell non-Hodgkin lymphoma (NHL). **A,** Posteroanterior chest radiograph; **B** and **C,** contrast-enhanced chest PET-CT images. Heterogeneous right anterior mediastinal NHL *(arrows)* extends across the midline *(open arrow)* and exhibits marked FDG avidity. A moderate right pleural effusion has developed.

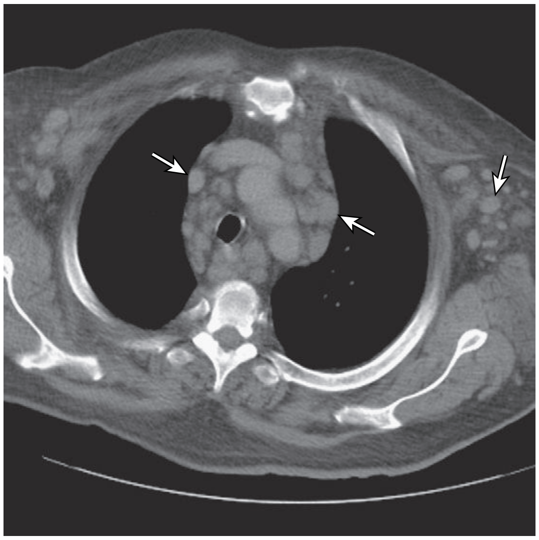

Figure 71-10 Unenhanced chest CT (mediastinal window) of patient with mediastinal non-Hodgkin lymphoma. NHL manifests as multiple enlarged mediastinal and axillary lymph nodes *(arrows).*

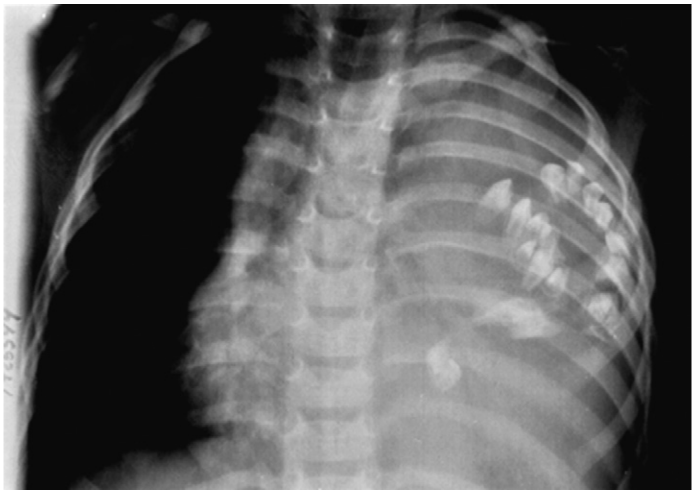

Figure 71-11 Posteroanterior chest radiograph of child with mediastinal mature teratoma. A large mass occupies the entire left hemithorax with mass effect on the mediastinum. Well-formed teeth within the mass, although highly specific for the diagnosis, are an extremely unusual finding.

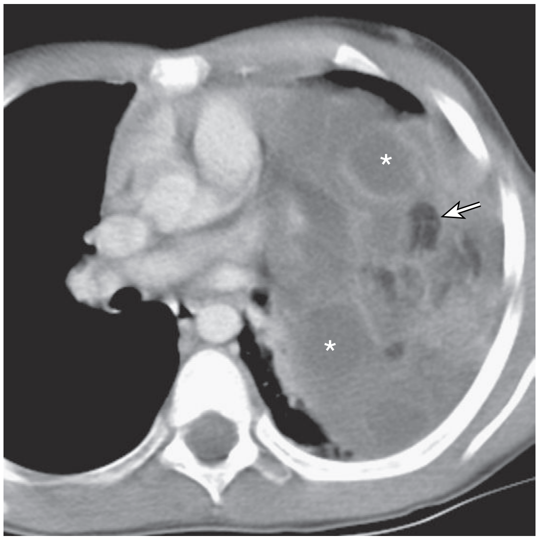

Figure 71-12 Unenhanced chest CT (mediastinal window) of child who has teratoma with immature elements. Teratoma manifests as a large, left anterior mediastinal mass with multicystic *(asterisks)* and fat *(arrow)* components.

untreated, aggressive NHLs are potentially more curable than indolent lymphomas. The treatment of indolent NHLs is palliative, and use of radiotherapy or chemotherapy depends on disease stage. PET-CT is an accurate method of assessing remission and prognosis after therapy of aggressive NHL.

Mediastinal Germ Cell Neoplasms

The most common primary extragonadal site of germ cell neoplasms is the anterior mediastinum. These lesions account for 10% to 15% of anterior mediastinal neoplasms in adults. Mediastinal germ cell neoplasms are a diverse group of benign and malignant neoplasms that may originate from ectopic primitive germ cells “misplaced” in the mediastinum during embryogenesis. Most neoplasms that occur in adulthood are benign, but childhood neoplasms are more often malignant. Adults in the third decade of life are most frequently affected. Benign, mature teratomas affect males and females equally, but most malignant mediastinal germ cell neoplasms affect males. Although malignant germ cell neoplasms that manifest as mediastinal masses are typically primary lesions, secondary neoplasia from a primary gonadal germ cell neoplasm should be excluded. Elevation of serum levels of tumor markers, such as alpha fetoprotein (AFP) and beta subunit of human chorionic gonadotropin (β-HCG), in a male with an anterior mediastinal mass strongly suggests the diagnosis of a malignant, nonseminomatous germ cell neoplasm.

Mediastinal Teratomas

Teratomas represent the most common mediastinal germ cell neoplasms, accounting for 60% to 70% of cases, and consist of tissues that may be derived from more than one of the embryonic germ cell layers. Most teratomas are well differentiated and benign, thus the term *mature teratoma*. Uncommon categories include immature teratoma and malignant teratoma or teratocarcinoma. Mature teratoma typically affects children and young adults. Although large tumors may result in symptoms related to local compression, patients with mature teratoma are frequently asymptomatic. Characteristic, but uncommon, symptoms include expectoration of hair (trichoptysis), sebum, or fluid as a result of communication between the tumor and the airways. Radiologically, teratomas are spherical, lobular, well-circumscribed, anterior mediastinal masses that may exhibit calcification on radiography (Figure 71-11). CT typically demonstrates a multilocular cystic mass, and 75% of lesions contain fat attenuation (Figure 71-12). The treatment of choice is surgical excision, and the prognosis is excellent.

Seminomas

Mediastinal seminomas typically affect men in the third and fourth decades of life and represent 40% to 50% of mediastinal malignant germ cell neoplasms of a pure histology. Most patients are symptomatic. β-HCG levels are elevated in 10% of the patients, but AFP level is normal in pure seminomas. The tumor manifests as a large, lobular, well-defined, anterior mediastinal mass. Invasion of mediastinal structures is uncommon, but lymph node, lung, and skeletal metastases may occur. Cisplatin-based chemotherapy for four cycles has largely

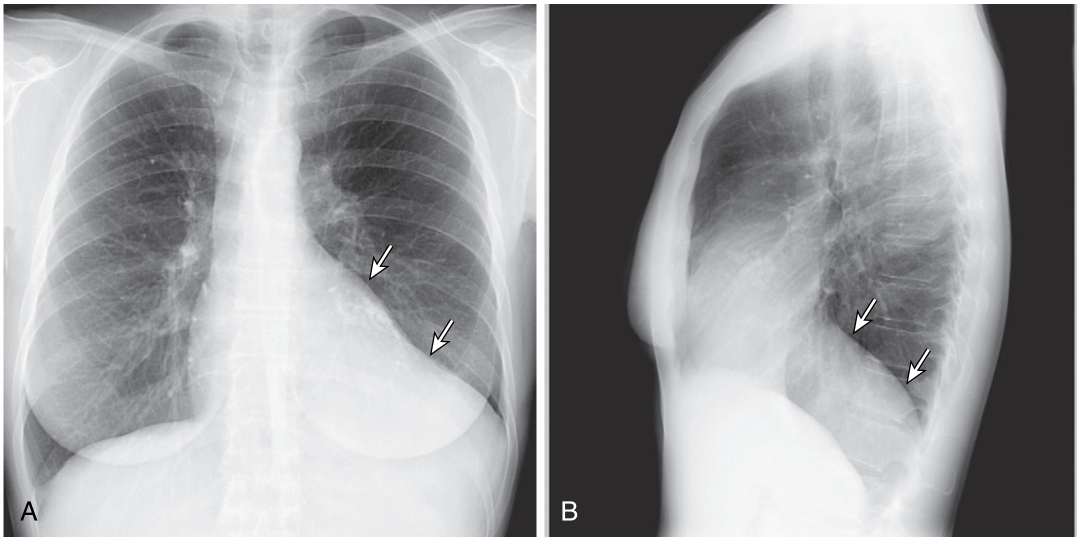

Figure 71-13 **A** and **B,** Posteroanterior and lateral chest radiographs of woman with thymolipoma. Large, soft, left mediastinal thymolipoma *(arrows)* conforms to lower left side of heart and diaphragmatic contours and exhibits multiple punctate calcifications.

replaced previously used radiotherapy alone and results in cure rates of approximately 80%. Radiotherapy is still used in combination with chemotherapy to treat bulky disease and residual neoplasm after chemotherapy.

Nonseminomatous, Malignant Germ-Cell Neoplasms

Nonseminomatous, malignant germ cell neoplasms affect young, symptomatic men and include choriocarcinoma, embryonal carcinoma, endodermal sinus (yolk sac) tumor, and mixed germ-cell neoplasms. Tumor markers (AFP and HCG) are elevated in most patients. A significantly elevated AFP level is usually found in endodermal sinus tumor and embryonal carcinoma, whereas HCG is typically elevated in choriocarcinoma. Nonseminomatous, malignant germ-cell neoplasms may be associated with various hematologic neoplasms, such as acute leukemia or myelodysplastic syndrome, and up to 20% of affected patients have Klinefelter syndrome. These tumors manifest radiologically as large, heterogeneous masses with internal low-attenuation areas corresponding to central necrosis, surrounded by enhancing nodular, irregular soft tissue. Invasion of adjacent structures, pleural and pericardial effusions, and lymph node and distant metastases are common.

Standard treatment involves systemic chemotherapy with cisplatin-containing regimens, followed by surgical resection of residual neoplasm if a positive response is achieved. Patients who respond to therapy are followed with serum tumor markers, which are expected to normalize after treatment. Compared with seminoma, the prognosis is less favorable; however, complete remission rates of 50% to 70% and 5-year survival of approximately 50% can be achieved in patients with nonseminomatous, malignant germ cell neoplasms.

Thymolipoma

Thymolipoma is a rare, benign thymic neoplasm composed of mature adipose and thymic tissues. It usually affects young adults and has no gender predilection. Thymolipomas grow slowly, frequently reaching a large size before diagnosis, and almost half of the patients are asymptomatic. Thymolipomas manifest as large, anterior, inferior mediastinal masses that conform to adjacent thoracic structures and may mimic diaphragmatic elevation and cardiac enlargement on radiography (Figure 71-13). These lesions may also exhibit positional changes in shape. CT and MRI demonstrate soft tissue and adipose tissue components and establish an anatomic connection between the lesion and the thymus (Figure 71-14). The treatment of choice is surgical resection. The prognosis is excellent.

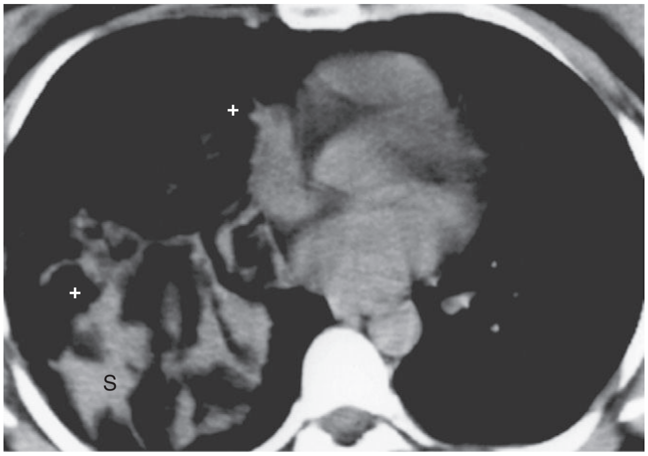

Figure 71-14 Unenhanced chest CT (mediastinal window) of a young woman with thymolipoma. Large anterior mediastinal thymolipoma drapes down into inferior right hemithorax. Note anatomic connection of the thymus and an admixture of fat (+) and soft tissue *(S)* elements within the lesion.

CYSTS

Thymic Cyst

Thymic cysts are rare anterior mediastinal masses that may be congenital or acquired. Congenital thymic cysts are usually found in the first two decades of life, whereas acquired thymic cysts are seen in association with the acquired immunodeficiency syndrome (AIDS) or thymic inflammation or malignancy (e.g., carcinoma, HD). Radiologically, thymic cysts are well-defined anterior mediastinal masses with cystic unilocular or multilocular appearances on cross-sectional imaging (Figure 71-15). Surgical excision is the recommended treatment. The diagnosis of cystic neoplasm should always be considered and excluded, and inflammatory cysts must be carefully examined to exclude associated malignancy.

Pericardial Cyst

Pericardial cysts, also termed *spring water cysts* or *clear water cysts* because of their clear-fluid contents, are uncommon developmental lesions that occur in the radiographic anterior mediastinum. Most are discovered incidentally in asymptomatic middle-aged adults. These cysts are well circumscribed and usually abut the heart, the diaphragm, and the anterior chest wall, typically in the right cardiophrenic angle. CT typically demonstrates a nonenhancing cystic mass of water attenuation and an imperceptible wall (Figure 71-16). Unless significant symptoms or atypical imaging features are found, pericardial cysts are followed clinically and radiologically.

GLANDULAR DISORDERS

Thymic Hyperplasia

Thymic hyperplasia most often occurs as a rebound phenomenon in patients who have received chemotherapy for treatment of lymphoma or germ cell neoplasms. Diffuse hyperplasia occurs within 2 weeks to 12 months after chemotherapy and may manifest with mediastinal enlargement on radiography or may mimic thymic neoplasia on cross-sectional imaging. On PET-CT, thymic hyperplasia typically exhibits only mild FDG uptake, in contrast to marked uptake by recurrent malignancy. Chemical-shift MRI (in-phase and out-of-phase gradient-echo sequences) may be used successfully to differentiate thymic hyperplasia from thymic neoplasia.

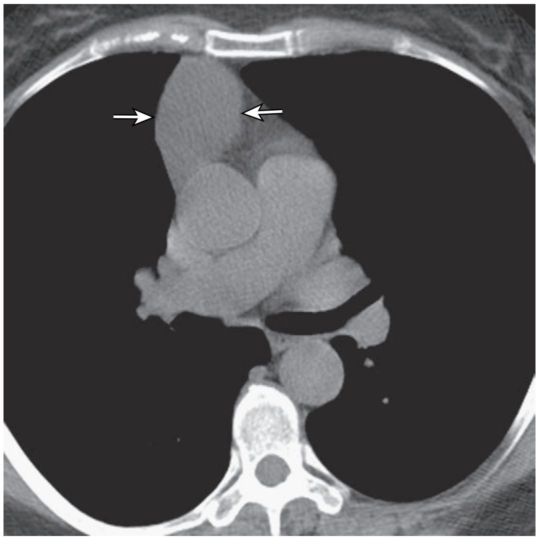

Figure 71-15 Unenhanced chest CT (mediastinal window) of asymptomatic woman with unilocular thymic cyst *(arrows)*, showing water-attenuation contents, an imperceptible wall, and no soft tissue component.

Intrathoracic Goiter

Most intrathoracic goiters result from extension of cervical thyroid goiters into the mediastinum and typically affect women. Although patients are usually asymptomatic, compression of the trachea or esophagus rarely causes symptoms such as dyspnea or dysphagia. The risk of malignant degeneration is small. Most intrathoracic goiters are located in the anterosuperior mediastinum, usually on the right side, but other compartments may be affected. Ectopic intrathoracic goiter without a cervical component rarely occurs. Chest radiography often reveals a cervicothoracic mass that produces mass effect on the trachea. CT demonstrates a lobular, well-defined mass with heterogeneous attenuation resulting from hemorrhage, cystic change, and calcification (Figure 71-17). Intense and sustained contrast enhancement is common. In functioning goiters, uptake of radioactive iodine (iodine 123 [^{123}I] or iodine 131 [^{131}I]) and technetium 99 m (^{99m}Tc) pertechnetate is diagnostic. Symptomatic or large goiters may be surgically excised.

Parathyroid Adenoma

Ectopic parathyroid glands in the mediastinum are usually located within or near the thymus gland. Most are encapsulated, functioning, benign adenomas, most often seen in older women who have persistent hyperparathyroidism after surgical parathyroidectomy. Because of their small size, parathyroid adenomas are rarely detected on chest radiography and frequently mimic lymph nodes on CT. Localization may be achieved by ^{99m}Tc sestamibi scintigraphy or dual-isotope digital subtraction imaging with ^{99m}Tc pertechnetate and thallium-201 chloride. Scintigraphic (functional) localization is correlated with CT or MRI (anatomic) identification of a mediastinal soft tissue nodule or mass. Selective venous sampling for parathyroid hormone levels may be necessary. Surgical excision is the treatment of choice.

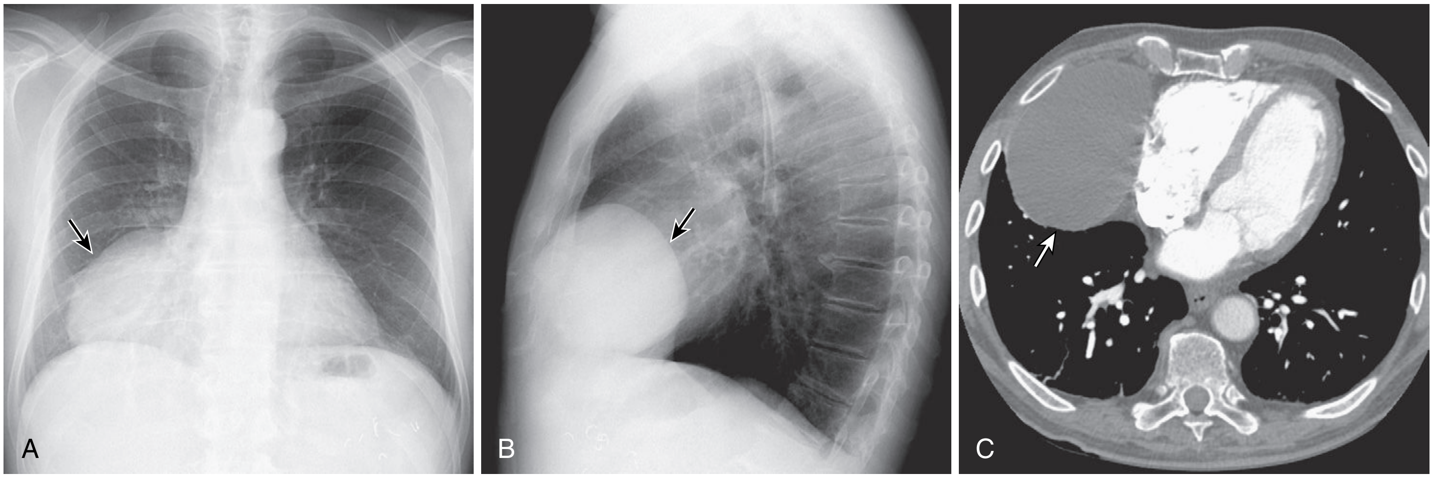

Figure 71-16 Pericardial cyst in asymptomatic man. **A** and **B,** Posteroanterior and lateral chest radiographs; **C,** contrast-enhanced chest CT (mediastinal window). Right cardiophrenic angle pericardial cyst manifests as a unilocular water-attenuation mass *(arrow)* with an imperceptible wall.

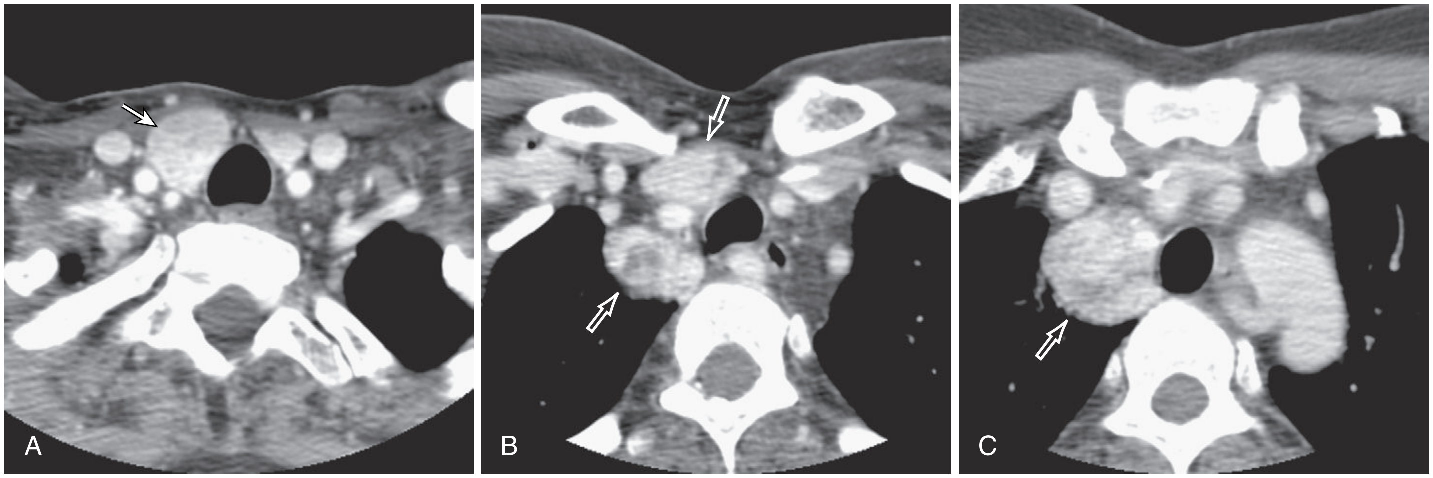

Figure 71-17 **A** to **C,** Contrast-enhanced chest CT (mediastinal window) in elderly woman with goiter *(arrows).* The goiter arises from right lobe of thyroid, extends into upper thorax, and exhibits exuberant contrast enhancement.

DISEASES OF MIDDLE-POSTERIOR MEDIASTINUM

LYMPHADENOPATHY

Benign Mediastinal Lymphadenopathy

Infectious and noninfectious granulomatous diseases may involve the mediastinal lymph nodes. Infectious granulomatous diseases include tuberculosis and fungal infections, such as histoplasmosis and coccidioidomycosis. The most important noninfectious granulomatous diseases include *sarcoidosis* and *silicosis*. Lymphadenopathy associated with granulomatous infection is usually unilateral and asymmetric, in contrast to bilateral and symmetric lymph node enlargement with sarcoidosis and silicosis. Many of these disorders cause lymph node calcification, which may exhibit an "eggshell" configuration, characteristic of silicosis and less often sarcoidosis. Although calcified lymph nodes generally represent a benign process, definitive exclusion of malignant lymphadenopathy may be impossible by CT alone, and histologic examination may be required.

Other benign causes of lymph node enlargement include reactive hyperplasia from bacterial or viral lung infections, amyloidosis, drugs such as phenytoin, and Castleman disease (angiofollicular lymphoid hyperplasia or giant lymph node hyperplasia). *Castleman disease* usually manifests in young, asymptomatic adults as incidental, large, well-circumscribed, middle-posterior mediastinal lymph nodes. Nodal hypervascularity results in intense, homogeneous enhancement after intravenous (IV) contrast administration on cross-sectional imaging. The hyaline vascular histologic type accounts for 80% to 90% of cases, whereas the plasma cell and multicentric types represent only 10%. Patients with the *hyaline vascular* type are typically asymptomatic, although symptoms of compression may occur. The *plasma cell* variety may be associated with constitutional symptoms and signs of fever, weight loss, fatigue, anemia, and hypergammaglobulinemia, which may improve after surgical excision. The *multicentric* type is rare and associated with severe systemic symptoms in older patients, generalized lymphadenopathy, and hepatosplenomegaly, with eventual development of NHL.

Metastatic Mediastinal and Hilar Lymphadenopathy

Primary lung, breast, renal cell, gastrointestinal, and prostate carcinomas and malignant melanoma may metastasize to mediastinal or hilar lymph nodes and may manifest as a solitary mass, a dominant mass with lymphadenopathy, or multifocal enlarged lymph nodes (Figure 71-18). Ipsilateral mediastinal metastases from lung carcinoma represent N2 disease and may be operable. The diagnosis of metastases is established by a history of a known primary malignancy and confirmed by biopsy. The treatment depends on the underlying neoplasm and its stage.

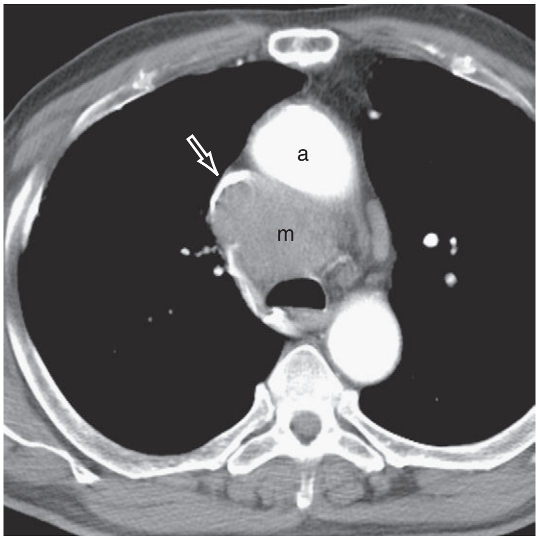

Figure 71-18 Contrast-enhanced chest CT (mediastinal window) in patient with mediastinal squamous cell cancer (SCCA) of lung. SCCA manifests as an anterior mediastinal mass *(m)* that insinuates between the ascending aorta *(a)* and trachea and invades the superior vena cava *(arrow).*

CYSTS

Foregut Cysts

Congenital foregut cysts represent 20% of mediastinal masses, and 50% to 60% of these are bronchogenic cysts. Enteric cysts, which include esophageal duplication and neurenteric cysts, account for approximately 10% to 15%. Up to 20% of foregut cysts cannot be histologically classified and are termed *nonspecific* or *indeterminate* cysts.

Bronchogenic Cysts

Bronchogenic cysts are thought to originate from abnormal ventral budding of the primitive foregut. Most are located in the mediastinum, most often in subcarinal or paratracheal locations. Up to 15% are reported to arise in the lung; other locations (pleura, diaphragm, pericardium) are rare. These cysts are usually lined by a pseudostratified, columnar, ciliated (respiratory) epithelium; exhibit cartilage and smooth muscle in their walls; and may contain serous fluid, mucus, milk of calcium, blood, or purulent material.

Bronchogenic cysts typically occur in adult men and women but may affect all age groups. Patients are usually asymptomatic, but infection or bleeding eventually produces symptoms in up to two thirds of cases. Radiography usually reveals a well-circumscribed, spherical, middle-posterior mediastinal mass. On CT, these cysts are unilocular homogeneous, nonenhancing masses of variable attenuation, depending on the composition of the fluid (**Figures 71-19** and **71-20**). The cyst wall may contain calcification or enhance after IV administration of contrast. A gas-fluid level within the cyst is exceptionally rare in mediastinal cysts but frequently occurs in pulmonary cysts and indicates communication with the airways or infection. Large cysts in children may compress the airways, with resultant atelectasis, bronchopneumonia, or air trapping.

The treatment of choice is surgical resection (even in the absence of symptoms), although incidental cysts in asymptomatic adults have been followed clinically and radiologically. Bronchoscopic or thoracoscopic needle drainage of cyst fluid typically reveals mucus and bronchial epithelial cells and is reserved for patients with a high risk of surgical complications.

Enteric Cysts

Enteric (esophageal duplication and neurenteric) cysts originate from the dorsal foregut, are usually located in the middle-posterior mediastinum or paravertebral region, and typically manifest in childhood. Enteric cysts are lined by squamous or enteric epithelium and may contain gastric mucosa and/or pancreatic and neural tissue. The cyst walls have two well-defined, smooth muscle layers with a myenteric plexus. *Esophageal duplication cysts* almost always adhere to the esophagus or are located within its wall and can be associated with gastrointestinal (GI) malformations. Similarly, *neurenteric cysts* may be associated with GI and cervical or upper thoracic vertebral anomalies, occasionally with a fibrous attachment to the spine or intraspinal extension.

Most enteric cysts are diagnosed during childhood. Hemorrhage or rupture may occur, especially when gastric epithelium or pancreatic tissue is present. The radiologic features of enteric cysts are similar to those of bronchogenic cysts. Esophageal duplication cysts are usually located close to the distal esophagus on the right side. Most neurenteric cysts are located in the paravertebral region, above the level of the carina on the right side, and approximately one half are associated with scoliosis, anterior spina bifida, vertebral fusion, hemivertebrae, and other vertebral anomalies. MRI is indicated to exclude intraspinal extension. Surgical excision is the treatment of choice. Prognosis after complete resection is excellent.

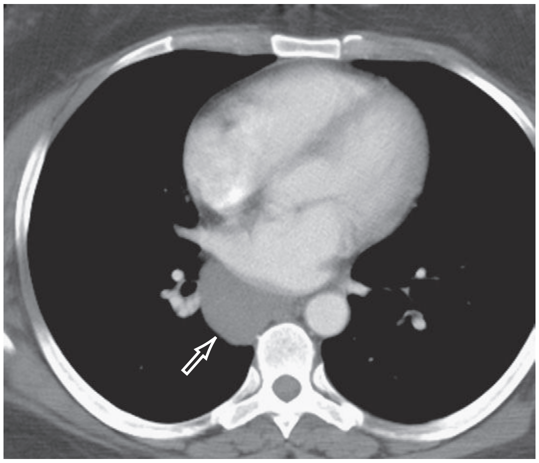

Figure 71-19 Contrast-enhanced chest CT (mediastinal window) of patient with bronchogenic cyst. The cyst *(arrow)* arises in azygoesophageal recess of middle-posterior mediastinum and exhibits water-attenuation contents with an imperceptible wall. Cyst contents do not enhance.

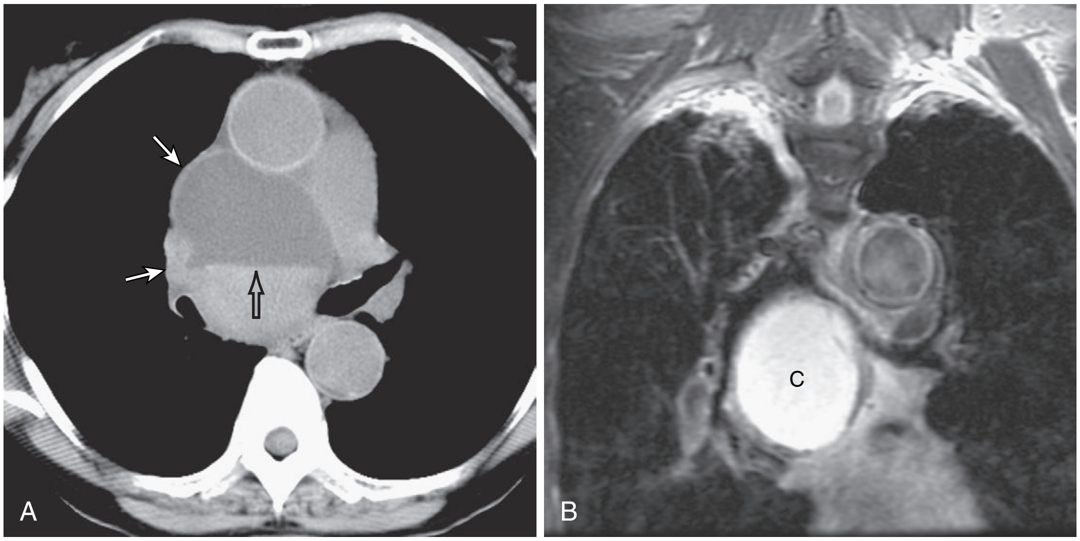

Figure 71-20 Subcarinal bronchogenic cyst. **A,** On contrast-enhanced chest CT (mediastinal window), the cyst *(arrows)* exhibits smooth mural enhancement and “fluid-fluid” level *(open arrow)* from recent hemorrhage. **B,** On T2-weighted coronal magnetic resonance imaging (MRI), the cyst *(c)* splays the main bronchi and exhibits high signal intensity.

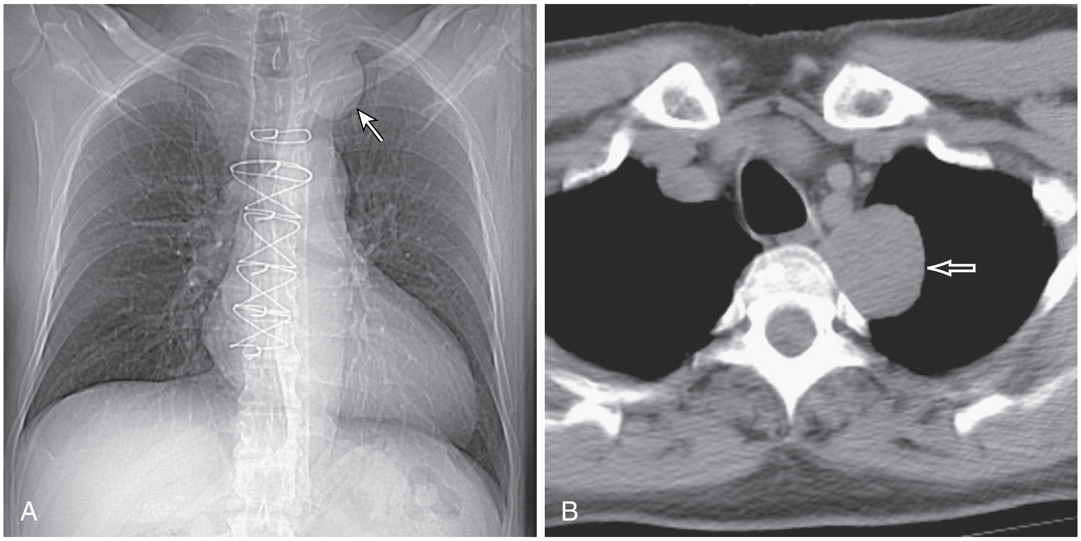

Figure 71-21 Neurofibroma. **A,** Posteroanterior chest radiograph; **B,** unenhanced chest CT (mediastinal window). Rounded, homogeneous left paravertebral neurofibroma *(arrow)* does not exhibit intraspinal extension or skeletal pressure erosion.

OTHER DISORDERS

Vascular Lesions

Vascular lesions constitute approximately 10% of all mediastinal masses and may originate from the arterial or venous portions of the systemic or pulmonary circulation. They may mimic neoplasms on chest radiographs and should be considered in the differential diagnosis before biopsy is performed. The diagnosis is usually established with contrast-enhanced CT, MRI, and angiography.

Herniation

Hiatal hernias are common and result when an abdominal structure, usually the stomach, extends through the esophageal hiatus into the thorax and manifests as a retrocardiac mass. *Morgagni hernias* are congenital defects in the diaphragm that allow herniation of omentum or other abdominal contents into the thorax and typically manifest as right cardiophrenic angle masses. Diagnosis is typically established by identification of abdominal contents in the hernia sac on cross-sectional imaging studies. Treatment of symptomatic cases is surgical.

DISEASES OF PARAVERTEBRAL COMPARTMENT

Neurogenic Neoplasms

Neurogenic neoplasms constitute 15% to 20% of adult and 40% of pediatric mediastinal tumors. Approximately 90% occur in the paravertebral region. Neurogenic neoplasms are the most common cause of a paravertebral mass and account for 75% of primary paravertebral "mediastinal" neoplasms. Approximately 50% of neurogenic neoplasms in children are malignant, whereas in adults most are benign. Approximately half of affected patients are asymptomatic. Neurogenic neoplasms are generally grouped into three categories according to their structure of origin: peripheral nerve, sympathetic ganglia, and paraganglionic neoplasms.

PERIPHERAL NERVE NEOPLASMS

Schwannoma and Neurofibroma

Schwannoma (also termed *neurilemmoma*) and neurofibroma are the most common mediastinal neurogenic neoplasms. More than 90% are benign, and 10% are multiple. They are slow-growing neoplasms and usually arise from a posterior spinal nerve root but can involve any nerve in the thorax. Schwannoma and solitary neurofibroma affect men and women equally in the third and fourth decades. Although these neoplasms may attain large sizes, most patients are asymptomatic. Approximately 30% to 45% of neurofibromas occur in individuals who have *neurofibromatosis* (von Recklinghausen disease). The presence of multiple neurofibromas or a single plexiform neurofibroma is pathognomonic of neurofibromatosis. Malignant transformation of a solitary schwannoma is extremely rare. Patients with neurofibromatosis and neurogenic neoplasms are at increased risk for malignant transformation of one or more lesions. Patients with neurofibromatosis may also have ganglion cell neoplasms develop.

Radiologically, schwannomas and neurofibromas are sharply marginated, spherical, and occasionally lobular paravertebral masses, which usually span one to two rib interspaces but can attain large sizes (Figure 71-21). Up to one half of the cases cause splaying and benign pressure erosion of the ribs, vertebral bodies, and neural foramina. Approximately 10% of schwannomas and neurofibromas grow through and widen adjacent neural foramina and expand on either end with a "dumbbell" or hourglass configuration (Figure 71-22). Typically, CT reveals a heterogeneous mass that may contain punctate calcification or areas of low attenuation. MRI should always be performed to exclude intraspinal growth of the neoplasm (Figure 71-23). The treatment of choice is surgery. Recurrences are uncommon, even when excision is incomplete.

Malignant Peripheral Nerve Sheath Neoplasms

Malignant peripheral nerve sheath neoplasms are a rare group of spindle cell sarcomas thought to represent the malignant counterparts of schwannomas and neurofibromas. These nerve sheath lesions occur equally in men and women in the third to fifth decades, and approximately half occur in patients with neurofibromatosis. The incidence of malignant degeneration of neurogenic neoplasms in patients with neurofibromatosis is approximately 5%. Malignant peripheral nerve sheath neoplasms may also occur sporadically or be induced by radiation. Pain and an enlarging mass are common at presentation. Radiologically, mediastinal malignant peripheral nerve sheath

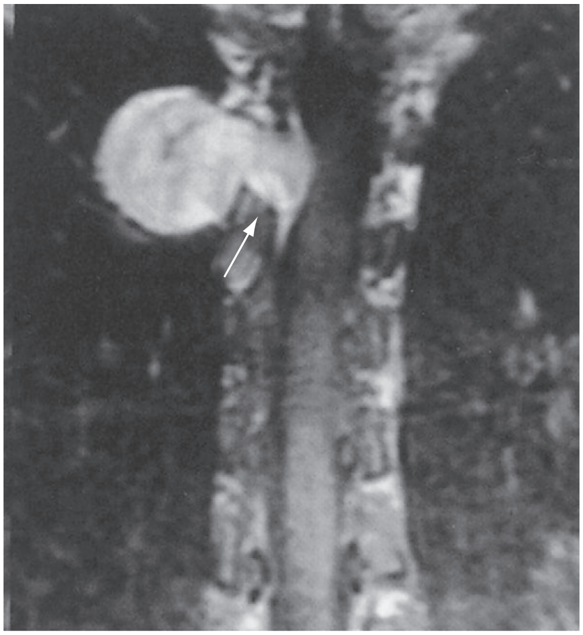

Figure 71-23 Gadolinium-enhanced T1-weighted coronal MR image of patient with neurofibroma. Spherical, heterogeneously enhancing paravertebral neurofibroma exhibits intraspinal extension *(arrow)* and mass effect on spinal cord.

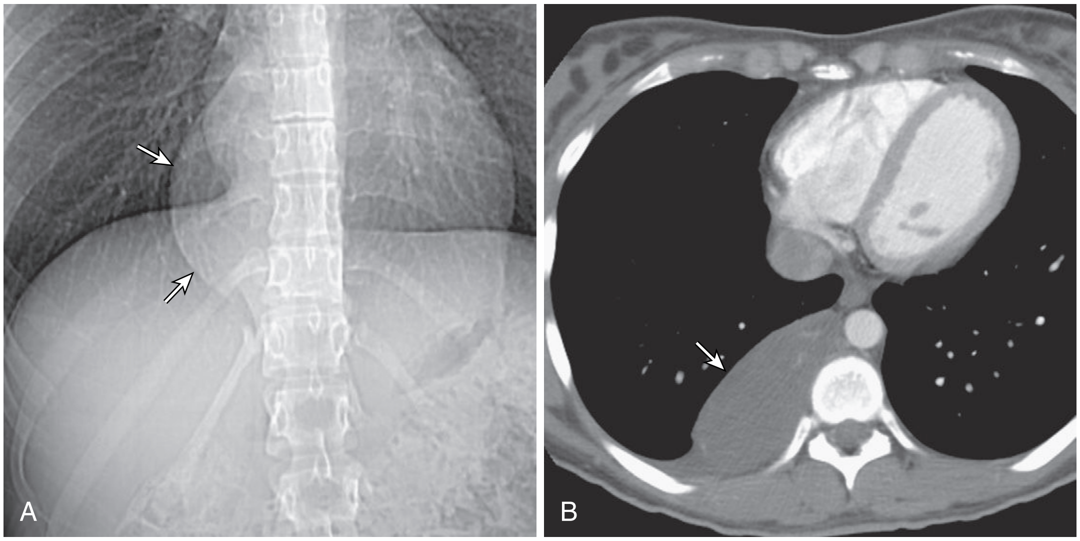

Figure 71-24 Ganglioneuroma in adolescent patient. **A,** Coned-down chest CT scout scan; **B,** contrast-enhanced CT scan (mediastinal window). Oblong, smooth, homogeneous paravertebral ganglioneuroma *(arrow)* does not exhibit intraspinal extension.

neoplasms manifest as sharply marginated, spherical, heterogeneous masses on cross-sectional imaging and may exhibit explosive growth.

SYMPATHETIC GANGLIA NEOPLASMS

Neoplasms of sympathetic ganglia affect both children and young adults, but malignant lesions are most common in children. Ganglioneuroma and ganglioneuroblastoma usually arise in the sympathetic ganglia of the paravertebral region. Approximately one half of neuroblastomas arise from the adrenal glands, and one third are located in the mediastinum, the most common extraabdominal location.

Ganglioneuromas

Ganglioneuromas are benign neoplasms that affect males and females equally. Affected patients are older children (typically >5 years of age) and young adults. One half of patients are symptomatic from local effects of the tumor or intraspinal growth. Radiologically, ganglioneuromas are well-circumscribed, oblong, paravertebral masses that usually span three to five vertebrae and may exhibit skeletal displacement or pressure erosion (Figure 71-24). MRI is indicated to exclude intraspinal extension. Surgical excision is the treatment of choice and may necessitate a combined thoracic and neurosurgical approach.

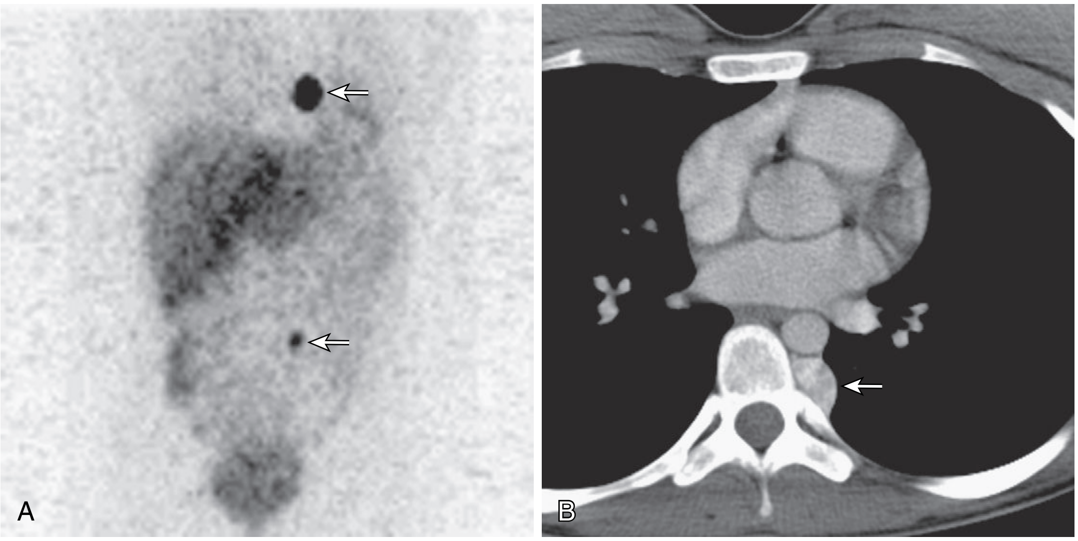

Figure 71-25 **A,** ^{131}I-MIBG scintigraphy of patient with pheochromocytoma. Two foci of pheochromocytoma *(arrows)* in the chest and abdomen exhibit marked uptake of radiotracer. **B,** Contrast-enhanced chest CT (mediastinal window) of left paravertebral pheochromocytoma, manifesting as a smooth nodule *(arrow)* with moderate enhancement.

Ganglioneuroblastomas

Ganglioneuroblastomas are malignant neoplasms that usually affect children younger than 10 years, with no gender predilection. They demonstrate composite histologic, biologic, and radiologic features of ganglioneuromas and neuroblastomas and are not usually distinguishable on imaging. Symptoms, when present, are caused by local mass effect, invasion of adjacent structures, or metastases. Staging and treatment are the same as for neuroblastomas. The prognosis for patients with ganglioneuroblastomas is generally more favorable than in those with neuroblastomas.

Neuroblastomas

Neuroblastomas are highly malignant neoplasms that affect children younger than 5 years, typically boys. Neuroblastomas in children older than 5 have no gender predilection. Two thirds of patients have constitutional symptoms, pain, cough, dyspnea, paraplegia, opsoclonus, and Horner syndrome. Systemic effects, such as hypertension, tachycardia, perspiration, flushing, and severe watery diarrhea, may result from elevation of catecholamine and vasoactive intestinal peptide levels. Radiologically, the masses are paravertebral, occasionally with local invasion, contralateral extension, and skeletal erosion. Approximately 10% exhibit extensive calcification on radiography. On CT, the tumors are heterogeneous because of hemorrhage and necrosis, and calcification may be detected in 80% of cases. MRI should always be used to exclude intraspinal extension and vascular or skeletal involvement. Metaiodobenzylguanidine (MIBG) scintigraphy (^{123}I or ^{131}I) may demonstrate uptake in both primary and metastatic sites.

Neuroblastomas and ganglioneuroblastomas are treated with surgical resection. Adjuvant chemotherapy and irradiation may be used for residual disease or as a primary treatment modality in advanced cases. Radiotherapy in children can lead to delayed complications such as myelitis and scoliosis. The prognosis is generally poor and depends on the age at diagnosis, the size, the degree of histologic differentiation, and the neoplastic stage. Patients with congenital and thoracic lesions have the best prognosis.

PARAGANGLIONIC NEOPLASMS

Pheochromocytoma

Pheochromocytomas are functioning paragangliomas that most often arise from the adrenal glands and occur more frequently in men in the third to fourth decades. Approximately 10% of pheochromocytomas are extraadrenal, and less than 2% are intrathoracic; the latter tend to be more aggressive and multicentric. Symptoms relate to excessive systemic catecholamines or local mass effect. Pheochromocytomas may be part of a multisystem endocrine syndrome (e.g., MEN IIA or IIB). Diagnosis can be established by measurement of urine catecholamines and their metabolites (vanillylmandelic acid, homovanillic acid, metanephrine, normetanephrine). Typically, CT and MRI reveal a well-delineated, enhancing, paravertebral mass. The neoplasm is typically ^{123}I and ^{123}I MIBG avid (Figure 71-25). Treatment includes sympathetic α- and β-blockade for 1 to 2 weeks, followed by surgical excision. Chemotherapy and radiotherapy can be used to treat metastatic disease.

Paraganglioma

Paragangliomas are rare neoplasms of paraganglionic tissue. Most are benign, asymptomatic, and nonfunctioning. Radiologically, they typically manifest as sharply marginated, middle-posterior mediastinal nodules or masses, usually located adjacent to the aorta, pulmonary arteries, heart, or costovertebral sulci or within the left atrial wall (Figure 71-26). Paragangliomas are hypervascular lesions and demonstrate marked contrast enhancement. The treatment is surgical excision.

SPINAL LESION

Lateral Thoracic Meningocele

Lateral thoracic meningoceles are rare and consist of redundant meninges that protrude through the neural foramen and contain cerebrospinal fluid (CSF). These meningoceles do not exhibit a gender predilection and typically occur in association with neurofibromatosis. Patients are usually asymptomatic adults in the fourth to fifth decades. Radiologic studies demonstrate a

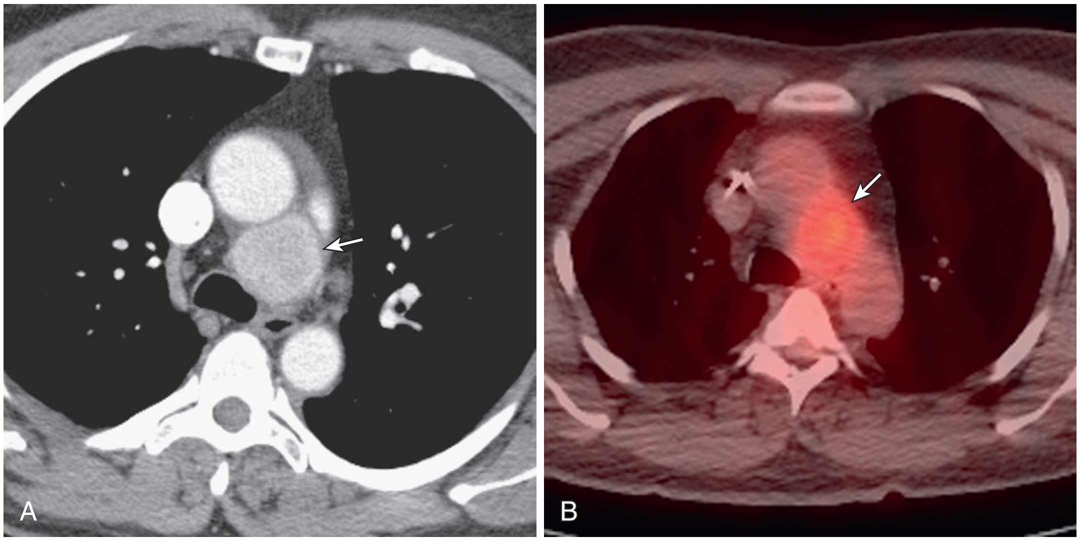

Figure 71-26 **A** and **B,** Contrast-enhanced chest positron emission tomography-computed tomography scan of patient with mediastinal paraganglioma *(arrow)* in the aorticopulmonary region, manifesting as a smooth, rounded mass with moderate homogeneous enhancement and FDG avidity.

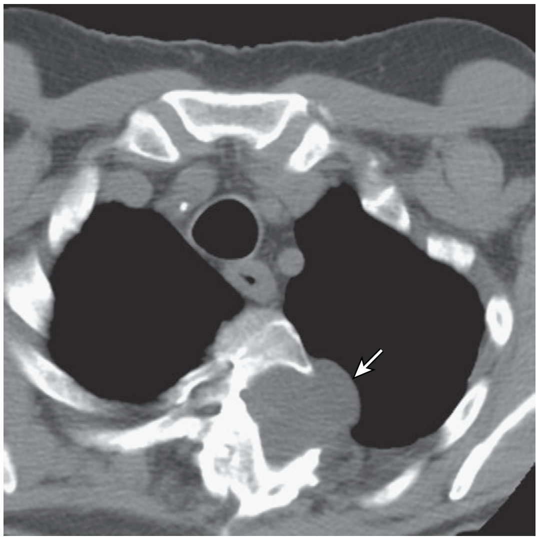

Figure 71-27 Unenhanced contrast CT (mediastinal window) of patient with lateral thoracic meningocele. The rounded meningocele *(arrow)* has attenuation that parallels that of cerebrospinal fluid, an imperceptible wall, and pressure erosion with expansion of neural foramen.

well-circumscribed, paravertebral, cystic lesion, frequently associated with vertebral erosion, kyphoscoliosis, and/or widening of adjacent neural foramina (Figure 71-27). Cross-sectional imaging may demonstrate continuity with the thecal sac. CT demonstrates a homogeneous nonenhancing mass of water attenuation, and MRI shows signal intensity equal to that of adjacent CSF. Symptomatic lateral thoracic meningoceles are treated with surgical excision.

MISCELLANEOUS DISORDERS OF THE MEDIASTINUM

Mediastinitis

The term *mediastinitis* is used to refer to a variety of infectious and inflammatory conditions. *Acute mediastinitis* is more common than the chronic form and may be caused by esophageal or tracheobronchial perforation, penetrating chest trauma, postoperative sternal wound infection, extension of an oropharyngeal infection or a paravertebral or vertebral abscess, radiation therapy, malignancy, and rarely anthrax. Patients with acute mediastinitis usually have had sudden onset of high fever, chills, chest pain, dyspnea, and dysphagia. Physical examination may reveal systemic toxicity, respiratory distress, Hamman sign, subcutaneous emphysema, chest wall tenderness, and edema. Chest radiography and CT show mediastinal widening, pneumomediastinum, mediastinal air–fluid levels or fluid collections, and pleural effusions. An esophagram may reveal perforation. Acute mediastinitis is a generally diffuse process but may be localized when secondary to sternal wound infection. The treatment includes surgical drainage, débridement, repair of the traumatic injury, and broad-spectrum antibiotics. The mortality rate is high, especially when the diagnosis is delayed.

Chronic mediastinitis, also termed *fibrosing* or *granulomatous* mediastinitis, is caused by various infectious and inflammatory processes. Histoplasmosis and tuberculosis account for most cases. Noninfectious causes include mediastinal hematoma, radiation therapy, and drugs such as methysergide and hydralazine. Chronic mediastinitis can be associated with various idiopathic and autoimmune diseases, such as retroperitoneal fibrosis, Riedel thyroiditis, pseudotumor of the orbit, sclerosing cholangitis, systemic lupus erythematosus, and rheumatoid arthritis. Dense fibrous tissue, usually located in the paratracheal, carinal, and hilar regions, compresses and obstructs mediastinal structures, such as the superior vena cava, pulmonary vessels, airways, and esophagus. *Superior vena cava syndrome* is the most common clinical manifestation. Chest radiographs, CT, MRI, and perfusion scintigraphy, in addition to endoscopy, help to suggest the diagnosis. The typical CT finding is an infiltrative mediastinal soft tissue mass with calcification and coexistent pulmonary or hepatosplenic calcified granulomas. Noncalcified lesions present a diagnostic dilemma and require exclusion of malignancy. Histologic examination of mediastinal tissue may be necessary to exclude a malignant neoplasm or active infection. Treatment is ineffective and mostly palliative; the benefit of corticosteroids is controversial. In the presence of viable fungal organisms or rising serum antibody titers, antifungal agents can be administered. For patients with superior vena cava syndrome, long-term anticoagulation and vascular stents may be effective.

Pneumomediastinum

Pneumomediastinum is typically caused by overdistention and rupture of alveoli because of increased intrathoracic volume or pressure that results from mechanical ventilation, blunt trauma, asthma, or spontaneous rupture. Air dissects along the pulmonary interstitium into the peribronchovascular tissues and mediastinum and frequently decompresses into the soft tissues of the neck. Less often, pneumomediastinum can be secondary to tracheobronchial or esophageal perforation, a gas-forming infection, traumatic direct entry of air, cervical soft tissue air, or pneumoperitoneum that tracks into the mediastinum.

Mediastinal Hemorrhage

Mediastinal hemorrhage can be spontaneous from rupture of a thoracic or other vascular aneurysm or dissection or can result from blunt or penetrating trauma or invasive medical procedures. Chest radiography typically reveals mediastinal widening. Unenhanced chest CT may show hyperdense areas within the mediastinum or aortic wall, and contrast-enhanced chest CT may reveal an intimal flap or dissection, a contained pseudoaneurysm, or frank extravasation of blood into the mediastinum, pericardium, or pleural space. The treatment depends on the cause and location of the source of bleeding and typically involves surgical repair, especially when the ascending thoracic aorta is involved.

DIFFERENTIAL DIAGNOSIS

Many mediastinal masses are benign and are found incidentally in asymptomatic patients. Large lesions may manifest with symptoms related to compression of adjacent structures. Aggressive or malignant neoplasms may produce constitutional symptoms, paraneoplastic syndromes, invasion of adjacent structures, or metastases. The radiologic evaluation of affected patients begins with chest radiography and is followed by cross-sectional imaging with CT and occasionally MRI. CT is useful in excluding vascular lesions and some benign causes of mediastinal widening, such as lipomatosis. In addition, confident diagnosis can be established for some lesions, including mature teratoma, mediastinal goiter, pericardial cyst, foregut duplication cyst, herniations, and lateral thoracic meningocele. Adjacent structures may also be evaluated for mass effect or invasion. Patients with primary mediastinal masses and cysts usually undergo surgical resection. The presence of lymphadenopathy (in patients with lymphoma and metastatic disease) or certain positive tumor markers may prompt limited biopsy sampling of the lesion, followed by oncologic consultation and chemotherapy with radiation therapy when appropriate. Resection of residual neoplasm will follow in some patients.

The most common *primary anterior mediastinal masses* are thymoma, substernal goiter, and lymphoma. All other lesions are extremely rare. In the correct clinical setting, patients with an anterior mediastinal mass should have serologic evaluation for detection of antibodies to acetylcholine receptors or elevation of AFP and β-HCG to exclude MG and nonseminomatous malignant germ cell neoplasm, respectively. Most primary thymic neoplasms arise in one lobe of the thymus and exhibit unilateral growth; thus an anterior mediastinal mass that extends across the midline is likely an aggressive neoplasm or diffuse malignant lymphadenopathy. Whereas thymoma typically manifests as a homogeneous unilateral thymic mass, *invasive thymoma* may exhibit irregular margins, invasion of mediastinal tissue planes and structures, and drop metastases. Mature teratoma typically manifests as a large, unilateral, multilocular cystic mass that often exhibits intrinsic fat and calcification. *Intrathoracic goiter* almost always results from contiguous extension of a cervical goiter. *Lymphoma* may affect any mediastinal compartment and classically manifests as lymph node enlargement. The diagnosis is frequently made by biopsy of a palpable peripheral lymph node, and mediastinal involvement is determined by cross-sectional imaging studies. Diagnostic problems may arise when lymphoma manifests with primary mediastinal lymphadenopathy or focal mass. Pericardial cysts are often followed clinically and on imaging.

Middle-posterior mediastinal masses include lesions from many causes. Mediastinal lymphadenopathy is common and may be of benign or malignant etiology to include lymphoma and advanced lung cancer. Mediastinal cysts are typically congenital, classically affect predominantly the middle-posterior mediastinal compartment, and are often surgically excised because of the high incidence of symptoms and complications. Radiologic characteristics can establish the diagnosis of congenital cysts in most cases.

Neurogenic neoplasms are common paravertebral masses. On the basis of morphology, patient age, and presence or absence of symptoms or associated conditions, a prospective diagnosis can usually be established. Lesions of *peripheral nerve* origin typically affect asymptomatic adults, have a spherical morphology, and are cured by excision. Multiple lesions suggest the diagnosis of neurofibromatosis. Neoplasms of *sympathetic ganglia* origin usually affect children and young adults, have an elongate morphology, and have a variable prognosis because of higher frequency of malignant histologic types. Preoperative assessment usually includes MRI to exclude intraspinal extension, with serum and urine catecholamines in some cases to exclude elevated levels and malignancy or clinically active neoplasms. Lateral thoracic meningoceles may mimic neurogenic neoplasms on radiography but are readily diagnosed on cross-sectional imaging.

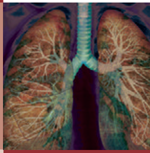
THORACIC SURGERY



Chapter 72

Chest Tube Insertion and Management

Stephen D. Cassivi • Claude Deschamps • Nicholas J. Pastis

The pleural cavity can require drainage when, in pathologic states, it contains air (pneumothorax), blood (hemothorax), serum (pleural effusion), lymph (chylothorax), or pus (empyema), or a combination of these. In the presence of these abnormal collections, the pleural cavity pressure may become positive, allowing the lung to collapse partially or fully, leading to hypoxemia. A common procedure used to drain air or fluid collections is the insertion of a chest tube (tube thoracostomy). A properly placed chest tube provides for drainage of air and/or fluid, reestablishes a negative intrapleural pressure, and allows the lung to reexpand within the pleural space. The correct management of a patient who needs a chest tube requires not only the skill to insert it safely, position it well, and minimize discomfort, but also the judgment to know when it is indicated and how to manage it properly after its placement. This requirement implies a sound knowledge of the principles of surgical drains and a working knowledge of the underwater seal drainage system being used.

INDICATIONS AND CONTRAINDICATIONS

Conditions associated with acute or severe respiratory compromise are considered absolute indications for chest tube placement and include tension pneumothorax, large symptomatic pneumothorax, hemothorax, empyema, and previous surgical violation of the pleural space (Box 72-1). In addition, under less clear-cut circumstances, appropriate judgment and experience will be required to help determine whether a chest tube is needed or not. Alternatives to chest tube placement, such as observation, thoracentesis, or formal operative drainage, must be considered and the choice individualized according to the clinical situation. Special caution is necessary when the patient's preoperative assessment findings point to an increased possibility of coagulopathy, intrapleural adhesions, or abnormal intrathoracic anatomy. The only contraindications to chest tube placement are a fused pleural space and lack of operative personnel with adequate experience in use of the technique for a safe and effective procedure. In considering placement of a chest tube, either of these circumstances should prompt consultation with a thoracic surgeon.

TECHNIQUE

The technique of chest tube insertion has been described in many publications. A focused yet comprehensive history and physical examination should precede any surgical procedure, even when it is done at the bedside. Chest radiographs and computed tomography (CT) scans, if available, should be thoroughly reviewed before and readily available during the procedure. When possible, a full discussion with the patient, including the specific indication, associated risks, alternatives, and postprocedural care, is indicated before proceeding with insertion of the pleural drain.

SELECTION OF DRAIN TUBE

At present, the most common tube used for chest drainage is a Silastic tube with multiple side holes. It usually has a linear radiopaque stripe running through the most proximal hole (allowing its location to be identified on chest radiographs) and markings to indicate distance in centimeters from the most proximal hole (Figure 72-1). These tubes range in size (gauge) up to 40 French (40F). Of note, some tube insertion kits come with a central trochar within the chest tube. Routine use of this trochar is unnecessary, can be dangerous, and is to be discouraged. Smaller chest tubes (14F or smaller) also are available, which can be placed using a Seldinger technique without the need for blunt dissection.

The size of the drain will depend on the indication for insertion and the size of the patient. In general, larger drains are more uncomfortable for the patient and more difficult to insert with use of local anesthesia. Conversely, smaller tubes usually are better tolerated by patients. Traditional consensus among experts has been that smaller chest tubes (14F or smaller) are more likely to clog with thick fluid or particulate matter, as encountered in a hemothorax or empyema, and are more prone to drainage problems from obstruction due to kinking of the tubing. Historically, a general rule has been that most collections are adequately drained with use of a 28F or 32F chest tube. Usually, a simple pneumothorax requires only a small chest tube (14F or smaller), although larger tubes (24F or larger) should be strongly considered for patients on positive-pressure ventilation.

Recently, however, a randomized controlled trial showed that in patients with pleural infection managed with use of smaller chest tubes (14F or smaller), duration of hospital stay, changes on the chest radiograph, and lung function at 3 months were no different from those in patients in whom larger chest tubes were used. In addition, no significant difference was observed in the frequency of either postprocedure death or requirement for thoracic surgery. Pain scores were substantially higher in patients receiving larger tubes. These results suggest that use of smaller-sized tubes may be preferable in the initial treatment of pleural infection.

Placement of long-term indwelling pleural drains also has become a commonly considered technique for the palliation of malignant pleural effusions. The specific technique and indications for use of these drains are discussed later in the chapter.

Box 72-1 Indications for Chest Tube Insertion

- Pneumothorax
  - Spontaneous
  - Traumatic
  - Iatrogenic
- Pleural effusion (hydrothorax)
  - Benign
  - Malignant
- Hemothorax
  - Traumatic
  - Iatrogenic
- Empyema
- Chylothorax
- Postoperative (cardiothoracic surgical procedures)

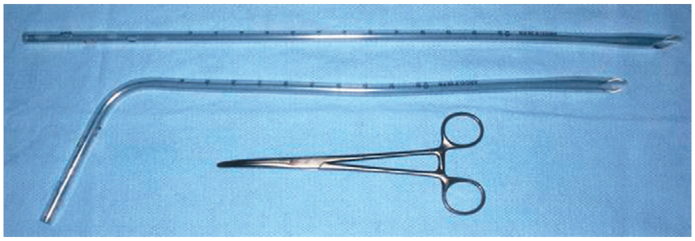


Figure 72-1 Silastic chest tubes. *Top to bottom*: Multiholed straight and angled Silastic chest tubes and Kelly clamp.

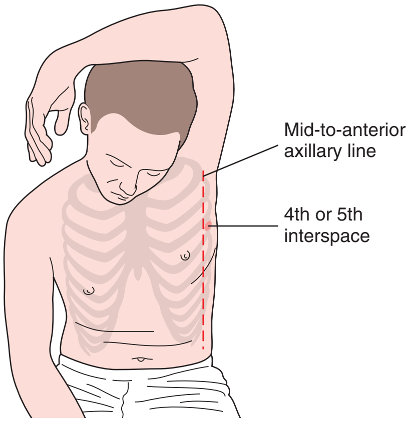

Figure 72-2 Preferred site for intercostal drain placement: at a point along the mid-to-anterior axillary line, in the fourth or fifth interspace.

DRAIN INSERTION SITE AND PATIENT POSITIONING

Generally, the optimal site for placement of a chest tube is through the fourth or fifth interspace in the anterior to midaxillary line just beyond the lateral edge of the pectoralis muscle and breast tissue (Figure 72-2). This insertion site has the advantage of relatively easy access and avoids the discomfort of a more posteriorly placed tube in patients who often are primarily lying supine in a hospital bed. In addition, it usually is high enough to avoid inadvertent subdiaphragmatic placement yet low enough to adequately drain fluid. Of note, in patients who are primarily lying supine in bed with free-flowing pleural fluid collections, the interspace level of placement of the chest drain is much less important than ensuring the posterior positioning of the tube within the pleural space. Placement of a chest tube in the second or third interspace anteriorly is to be avoided if possible. Such placement does not provide any advantage over the lateral position described previously and is significantly more painful and disfiguring for the patient.

For elective chest drain insertion, the patient should be kept in a relatively comfortable position that facilitates placement of the tube in the location described earlier. Usually, this can be achieved by placing the patient supine or in a semi-Fowler position (with thorax and head elevated 30 to 45 degrees) with the involved side elevated approximately 30 to 45 degrees on wedges or pillows. To improve access to the lateral chest wall, the patient's arm on the involved side is brought above the head (Figure 72-3). As with most thoracic procedures, the operator should stand at the patient's back.

PREPARATION, ANESTHESIA, AND INCISION

Before positioning of the patient, all necessary equipment should be made available (Box 72-2). A deliberate pause should be taken to verify the patient's identity and to confirm the procedure and correct operative side. When possible, the most recent chest radiograph should be posted in a readily visible location as a separate safety measure to avoid wrong-sided procedures.

The chest wall is cleansed with antiseptic solution and draped in such a way as to provide an operative field approximately 20 cm by 20 cm in size. The skin is infiltrated with 1% lidocaine at the chosen site of insertion with use of a 21-gauge

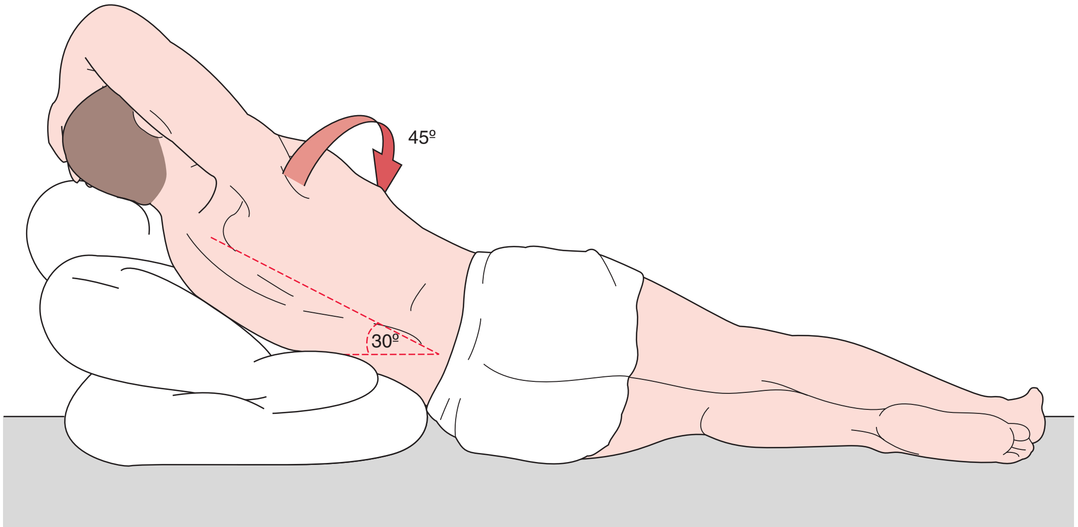

Figure 72-3 Patient positioned for intercostal drainage. The trunk is elevated on pillows to a 30-degree angle and rotated by 45 degrees.

Box 72-2 Instrument Requirements for Chest Tube Insertion

- Sterile gloves and gown
- Antiseptic solution with swab applicators
- Sterile drapes or towels
- 20-mL syringe
- 21-gauge needle
- 18-gauge needle
- 1% lidocaine
- Scalpel with blade
- Needle driver
- 0-0 silk suture (on cutting needle)
- Kelly clamp
- Chest tube
- Underwater seal chest drainage system
- Gauze and dressing material

needle. Further generous infiltration of the subcutaneous tissues can be done with use of a large-bore needle (18-gauge). Aspirating before injection with this needle will prevent inadvertent vascular injection, as well as indicating the direction and depth of the parietal pleura. The parietal pleura are extremely sensitive and must therefore be thoroughly anesthetized.

A 2-cm transverse incision is made with the scalpel. The incision usually is made one interspace below the interspace planned for insertion, to allow "tunneling" over the superior border of the lower rib. At this stage, one stitch of 0-0 silk suture can be placed at the posterior margin of the incision and tied down, leaving the two ends even and uncut. This suture will be used later to secure the chest tube. Placing the stitch at this point, before initial dissection and entry into the pleural space with its requisite drainage of fluid or air, is much easier. It allows for much more efficient securing of the chest tube once in place within the pleural cavity. In an obese patient, it may be necessary to increase the size of the initial skin incision to permit adequate palpation of the ribs and interspaces.

DRAIN INSERTION

After completion of the initial incision and placement of the securing stitch, a curved Kelly clamp is used to dissect a tract for the chest tube within the subcutaneous and intercostal tissues. "Tunneling" of this tract over the superior border of the lower rib prevents damage to the intercostal neurovascular bundle that lies along the inferior border of each rib. It also reduces the likelihood of air leak at the time of chest tube removal and thereafter while the incision site heals.

Dissecting by use of the Kelly clamp is done with incremental spreading and advancement of the clamp to create a tract for the chest tube. It is important to dissect along only one tract, to avoid subsequent difficulties in finding the dissected path at the moment of tube insertion. This precaution is especially relevant in obese patients. The pleura can be very taut or thickened and can sometimes present significant resistance to entry. Extreme care must be taken on entering the pleural cavity with the Kelly clamp, to control its forward progress and prevent inadvertent entry into underlying structures. Entry into the pleural cavity is signaled by egress of air or fluid and sudden decrease in resistance to forward movement of the clamp. For the patient, breaching of the parietal pleura usually is the most uncomfortable part of the procedure, and it often is useful to provide further local anesthetic to the area before piercing the pleural cavity.

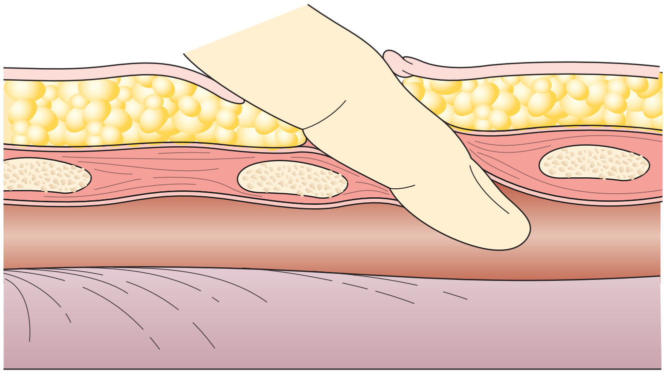

Figure 72-4 For optimal drainage tube placement, the operator's index finger is inserted along the drain tract to exclude adhesions and confirm entry into the chest cavity. Notice that the tract has been created in the interspace over the upper surface of the rib.

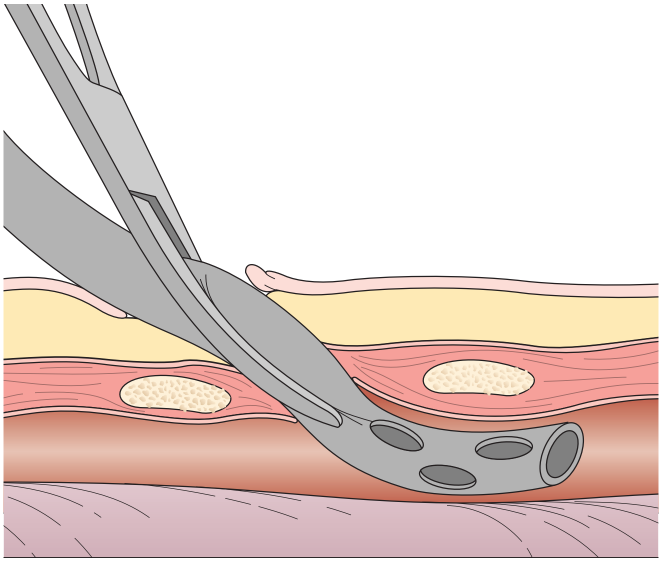

Figure 72-5 Use of a Kelly clamp to guide drain insertion.

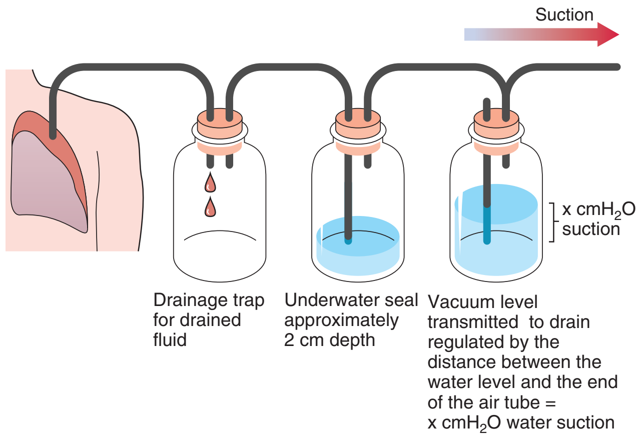
Once the parietal pleura have been breached, the clamp is withdrawn in the open position. The next step is to insert the operator's index finger into the pleural cavity to ensure pleural entry (to exclude subdiaphragmatic placement) and assess for the presence of pleural adhesions and pleural lesions or nodularity (Figure 72-4). The chest tube can then be guided into place by use of the Kelly clamp, as illustrated in Figure 72-5. Careful placement is an important part of the procedure and, regrettably, often is rushed because of either patient discomfort or ongoing fluid or air leakage. Proper functioning of the tube requires that care be taken at this point to deliberately direct the tube in the desired position. In the most common scenario, in a patient who will for the most part be supine, the tube should be guided posteriorly and then directed cephalad. A tube positioned in this fashion will drain both air and fluid satisfactorily in most cases. To ensure a posterior placement of the drain, the tip of the tube, once in the pleural cavity, must be deliberately directed posteriorly before being advanced. Failure to perform this specific maneuver often will lead to malposition of the tube, either in an anterior direction or within the major fissure, which will then function poorly.

Once the chest tube is positioned correctly, it can be secured in place with the previously placed suture and connected by tubing to the underwater seal chest drainage system



Suction
x cmH$_2$O suction
Drainage trap for drained fluid
Underwater seal approximately 2 cm depth
Vacuum level transmitted to drain regulated by the distance between the water level and the end of the air tube = x cmH$_2$O water suction

Figure 72-6 Underwater seal chest drainage system. Commercially available systems incorporate a multichamber device in one casing that includes (1) a collection chamber to collect fluid and particulate drainage; (2) a waterseal chamber and manometer to ensure one-way egress of air from the pleural space and monitor intrapleural pressures; and (3) suction regulator to control the level of intrapleural suction being applied.

(Figure 72-6). A light dressing is applied to the drain site, and a chest radiograph is obtained to confirm proper tube placement.

CHEST TUBE MANAGEMENT

Specific chest tube management usually is predicated on the condition initially requiring chest drainage. It is nonetheless important to consider the general principles of chest tube management, as well as specific situations that require a particular remedy or response.

GENERAL PRINCIPLES

Once inserted, the chest tube should be closely monitored for the nature (air, fluid, or both) and quantity (slight, moderate, or large air leak or volume of fluid) of pleural drainage. Changes in these parameters, especially if abrupt, should be noted, because they provide important information regarding current pathologic status in the pleural space or drainage system malfunction. The amount of fluid drained hourly should be recorded.

Suction usually is applied to the underwater seal device initially after tube placement, to promote drainage and ensure a negative intrapleural pressure. The amount of suction applied usually is −20 cm of water. It should be emphasized that suction is provided by the underwater seal device and is never directly applied to the chest tube; the former is controlled, whereas the latter may lead to pulmonary or vascular injury. Suction usually can be discontinued and the patient's tube left on "water seal" early in the course of chest tube management if drainage is adequate and the pleural process is resolving. Under certain circumstances, chest tube suction is to be avoided—for example, with placement of a chest tube after a pneumonectomy, or in patients with emphysema and a prominent air leak, such as after lung volume reduction surgery.

A number of observable clues to the functional status of the chest tube and the current status of the pleural space are recognized. Oscillations ("tidaling") of the fluid levels in the water seal or tubing leading to the water seal that are synchronous with the patient's respiratory cycle demonstrate the chest drain is patent and communicating with the pleural space. It also indicates that the lung has not completely reexpanded to fill the entire pleural space. The situation in which fluid is allowed to pool in dependent portions of tubing connecting the chest drain to the underwater seal device is to be avoided. This condition creates an increased resistance to proper drainage of air and will delay the resolution of the intrapleural process. This problem can be avoided by educating the nursing staff to this potential problem and having them intermittently drain the dependent loop of tubing.

AIR LEAK

When bubbling is observed in the underwater seal device, especially if this is a new or unexpected finding or if the bubbling is continuous (not in cycle with respiration), a thorough survey of the drainage apparatus must be undertaken. An air leak occurring anywhere in the tubing, from the insertion site at the skin to the underwater seal device, as well as any connectors in between, can cause bubbling to appear in the water seal chamber. This can be assessed by placing a clamp on the tubing as near to the insertion site as possible. Bubbling will continue when there is a leak in the tubing. The location of the tubing breach can be found by sequentially moving the clamp toward the underwater seal device and checking at each application for continued bubbling. Air leaks often occur at the connection joint of the chest drain to the underwater seal device's tubing. Once the leak has been located, the damaged tubing or connector should be replaced. The practice of taping the tubing connection joints probably will not prevent or treat occult air leaks but may be useful in reducing the incidence of inadvertent disconnection of the tubing. Unfortunately, a disconnection can still occur, and it may not be as easy to notice underneath a layer of tape. At our hospital, this practice has been replaced with the "banding" of each connection point with a disposable circumferential ratcheted plastic appliance.

CHEST TUBE CLAMPING

In general, chest tube clamping should be avoided. In a few instances, clamping may be necessary or can be a useful adjunct in tube management. Chest drains should be clamped proximally (nearer to the patient) during changing of the tubing or underwater seal device. "Diagnostic" clamping also may be necessary to troubleshoot a continuous air leak when a leak in the tubing system is suspected. Chest tube clamping at the time of drain insertion to prevent reexpansion pulmonary edema is described later in this chapter.

Before removal of a chest tube that has an intermittent or persistent low-grade leak or a wide oscillation of fluid in the tubing, it may be useful to simulate chest tube removal by clamping it for a short period of time (1 to 2 hours). A chest radiograph is then obtained. If the lung remains expanded and there is no evidence of increasing subcutaneous emphysema despite the tube's being clamped, the chest tube can then be removed. If, however, the radiograph shows a pneumothorax or increasing subcutaneous emphysema, or if the patient becomes symptomatic with shortness of breath or pain, the clamp should be promptly removed. Patients in whom the chest tube is clamped for this reason must be closely monitored for symptoms and clinical signs of worsening dyspnea or reaccumulation of the pneumothorax. Routine use of tube clamping before chest tube removal is unnecessary.

CHEST TUBE REMOVAL

Chest tubes are removed when the indication for their placement has resolved: when air leaks have stopped, fluid loss has diminished to a minimal rate (usually less than 300 mL/24 hours), and chest radiography shows the lung to be well expanded. Patients still requiring positive-pressure ventilation with high peak airway pressures are at high risk for new or recurrent air leaks because of barotrauma. In these situations, a chest tube that otherwise would be removed because it has accomplished the drainage for which it was placed should be left in place until the patient has been extubated or the risks of barotrauma have been minimized.

Many techniques are described for chest tube removal, but we recommend the following sequence: After the drain stitch holding the tube in place at the skin has been cut, the patient is asked to take as deep a breath as possible and hold it. Once the patient reaches maximal inspiration, the drain is gently yet swiftly removed. An airtight dressing is then applied to the drain exit site. In our own practice, this method has proved to be the most reliable way to avoid ingress of air into the pleural cavity during chest tube removal. At maximal inspiration, the portion of the respiratory cycle with the most negative intrapleural pressure has been completed. Then, if the patient experiences any discomfort during the removal of the chest drain, the only possible respiratory maneuver at this point will be exhalation, causing increased positive intrapleural pressure and favoring egress of any pleural air.

Some clinicians emphasize the need for a pursestring or mattress stitch to be placed at the time of tube insertion so that this can be tied down at the time of drain removal to ensure wound closure. In our experience, this is not an absolute necessity, and we do not routinely use this adjunctive technique. This technique may potentially be useful in situations in which the chest tube has been in place for several weeks. Although it assists in securing a closure to the drain site, presence of this suture is associated with increased pain after drain removal and requires an early return visit to remove the stitch, 5 to 7 days later.

SPECIAL CONSIDERATIONS

INSERTION DIFFICULTIES

Negative Aspiration

The best opportunity to drain a pleural space is at the time of initial tube insertion. As mentioned previously, needle aspiration at the time of local anesthetic administration allows for confirmation of the presence of air or fluid. If, during needle aspiration, no air or fluid is encountered, further attempts should be made through higher and lower interspaces. If neither air nor fluid (as appropriate) is found, the procedure should be postponed and the situation reevaluated. Further imaging using imaging-guided techniques, for example, or with a more experienced hand, may be required. Failure to follow these precautions may convert a minor difficulty into an emergency, with inadvertent insertion of a drain into the lung or other viscera.

Intrapleural Adhesions

Patients with previous ipsilateral cardiothoracic procedures or a history of a previous pleural process are at increased risk for formation of significant pleural adhesions. These factors should always be taken into consideration in decisions regarding placement of a chest tube. Intrapleural adhesions are detected by palpation. If thin and flimsy, they often can be swept away sufficiently, using the operator's finger, to allow the drain to be inserted safely. If the adhesions are stout, they should be left in place, because further attempts to take these down by finger sweeping may cause tearing and bleeding of the lung or pleural surfaces. The chest tube often can still be inserted and advanced gently to find its own way around various areas of adhesion. If, however, a complete pleural symphysis is encountered, the procedure should be aborted and its indications reconsidered.

Subdiaphragmatic Placement

A chest tube may be incorrectly placed under the diaphragm if the insertion site is chosen too low on the chest or if the diaphragm is elevated higher than expected. This error occurs usually when the operator incorrectly interprets a lower chest opacification as fluid rather than considering the possibility of a raised hemidiaphragm. This mistake usually can be identified when the operator performs finger palpation after breaching the "pleura." If no intraabdominal injuries have occurred, the insertion site can simply be closed, and a higher insertion is then undertaken. Careful monitoring for abdominal injuries is continued after the procedure is properly completed.

This error can be avoided with the recognition that most patients will be for the most part supine during the course of chest drainage after the tube is inserted. Therefore, in free-flowing pleural fluid collections, the positioning of the tube in the pleural space posteriorly is much more important than a low-lying insertion site, which increases the risk of subdiaphragmatic placement.

Impaled Structure

An impaled structure necessitates urgent surgical referral. As with many complications, the optimal management in this situation is to take every measure possible to prevent occurrence of this mishap. As mentioned previously, the use of trocars to assist with chest tube placement may predispose to this type of injury. The use of the technique of blunt finger palpation to guide the drain insertion will avoid this serious injury in most cases.

DIFFICULT MANAGEMENT ISSUES

Subcutaneous Emphysema

Subcutaneous emphysema is a result of leakage of air under sufficient pressure to track into the subcutaneous tissues. As with any gas or fluid, air under pressure will seek the exit path of least resistance. If a chest drain is occluded either by kinking, clamping, or clogging of the tubing with fibrinous material or clot, continued air leak from the pulmonary parenchyma will seek a different path of exit from the pleural space. This also can occur if a volume of "stagnant" fluid remains in a dependent loop of the connecting tubing, as described previously. The increased intrapleural pressure will promote lung collapse and subsequent tracking of air through breaches in the parietal pleura into the subcutaneous tissues.

If subcutaneous emphysema develops, a thorough evaluation of the tubing and collection system is indicated. A chest radiograph is important to assess the lung. Any obstruction within the tubing must be cleared to favor egress of air through the drain over any other pathway. An initial maneuver to consider is to restart suction on the drain by means of the underwater seal device. If the tubing is patent, restarting suction may be all that is needed. Evaluation of the pleural space with computed tomography (CT) may help identify the area

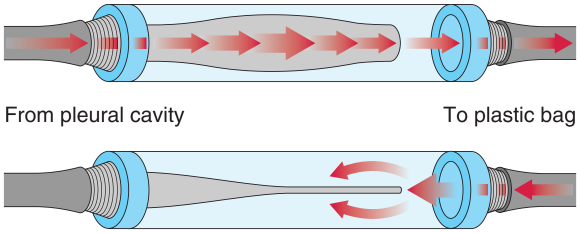


Figure 72-7 Heimlich valve. Air expelled from the pleural cavity opens the flutter valve (*upper*); when pleural pressure falls below atmospheric pressure, the flutter valve is compressed and sealed to prevent inflow of air.

requiring further drainage. The parenchymal air leak may be of such magnitude that a second chest tube is required. On rare occasions, surgical repair of the air leak may be necessary.

Subcutaneous emphysema can be quite disfiguring and thus extremely distressing to affected patients and their families. Appropriate management should therefore include reassurance that although dramatic in appearance, this is rarely a dangerous situation, that the condition usually will require more time to resolve than it took to appear, but that it will ultimately resolve.

Prolonged Air Leak

A prolonged air leak usually is defined as one that persists for more than 1 week. This problem may be secondary to a number of causes. If the air leak is not amenable to surgical repair and is expected to eventually heal spontaneously, a prolonged hospital stay often can be avoided with the use of a Heimlich valve (Figure 72-7). As an integral component of a passive drainage system, this one-way flutter valve allows air and fluid to be expelled from the chest cavity while preventing air from entering the pleural space. The patient can be discharged with instructions to return on a weekly basis for a chest radiograph to evaluate the resolution of the air leak.

Special attention must be paid to the attachment of the Heimlich valve to ensure that it is attached in the proper direction. Otherwise, air can be trapped in the pleural space, leading to collapse of the lung and creating the potential for a tension pneumothorax.

Drain Obstruction

Occasionally, a chest drain may become occluded with fibrinous debris or frank clot. If the intrapleural process initially warranting chest tube placement has not resolved, the chest tube occlusion must be cleared. This often can be achieved by "milking" or stripping the tubing. It should be recognized that such stripping of the tubing can create transient negative intrapleural pressures in excess of 400 cm H_2O. This maneuver is of questionable benefit and should therefore not be undertaken without the knowledge and consent of the primary surgeon or physician responsible for the chest tube. Another way to clear intraluminal blockage from the chest tube is to pass a Fogarty embolectomy catheter in retrograde fashion up the tube and then draw it back with the balloon inflated, thereby pulling out the debris. This should, of course, be done using meticulous sterile technique. If, after using the appropriate techniques described previously, the drain remains occluded, a new drain may need to be inserted and the occluded drain removed.

Failure of the Lung to Reexpand

After insertion of a chest tube, a frontal (anteroposterior) chest radiograph should be obtained to assess positioning of the tube and resolution of the intrapleural process that required drain placement. If the lung has not fully reexpanded, an explanation must be sought from among the following scenarios.

First, in the case of a large air leak or initially after lung resection, the lung may not have had enough time to fully reexpand, and no immediate action is necessary. Otherwise, proper intrapleural placement must be confirmed. Definitive confirmation may not be obtainable with the two-dimensional radiograph. It should, however, identify whether all of the chest tube holes are within the pleural space. If this is not the case, the tube may be drawing outside air into the pleural space and tube, thus preventing full reexpansion of the lung. A new sterile tube will then need to be inserted. If the radiograph suggests that all drain holes are appropriately within the pleural space but the lung still is not fully expanded, the explanation may be extrapleural insertion of the tube. Observing a complete lack of any drainage (air or fluid) or oscillation in the tubing can identify this problem. A lateral chest radiograph can help to confirm an intrapleural location of the tube; however, CT is more sensitive.

In cases of hemothorax, chronic pleural effusion, or empyema, the underlying lung may not be able to fully reexpand because of formation of a fibrinous peel or rind overlying the visceral pleura. Drainage of the fluid collection may be complete, yet it leaves an unresolved intrapleural space. If this space does not resolve over the course of a few days of suction applied to the chest drainage tube, surgical decortication may be necessary. Alternatively, bronchoscopy may be indicated to exclude endobronchial blockage preventing reexpansion of the underlying lung parenchyma.

Reexpansion Pulmonary Edema

For drainage of a large intrapleural fluid collection that is compressing underlying lung, consideration should be given to the extremely rare but potentially lethal phenomenon of *reexpansion pulmonary edema*. This pathologic process is due to rapid reexpansion of the previously compressed lung at the time of fluid drainage, leading to a rapid increase in blood flow and pulmonary capillary pressure. Consequent fluid shift across the capillary and alveolar membranes leads in turn to formation of excess extravascular fluid.

The first sign of this process usually is noted at chest tube insertion, when fluid drainage is rapid, at which point the patient begins to cough uncontrollably. Onset of coughing usually occurs when between 800 and 1500 mL of fluid has been acutely drained. When this is observed, the chest tube should be immediately clamped. This maneuver usually will control the patient's urge to cough and prevent further progression of the underlying pathologic process. A controlled drainage is then performed by intermittently unclamping the tube until resolution of the effusion is observed.

Septated Pleural Fluid Infections

In some patients with pleural infections, chest tube drainage may be curtailed or even blocked entirely by the presence of septations, leading to incomplete drainage of fluid through the tube. The breakdown of such septations with the use of fibrinolytic agents may result in improved pleural drainage.

Despite positive results in observational studies, randomized controlled trials of treatment with single fibrinolytic agents have surprisingly not shown a benefit over standard chest tube drainage. However, a randomized controlled trial has demonstrated that the use of combined intrapleural tPA and DNase delivered through chest tubes improved fluid drainage in patients with pleural infections, reduced the frequency of surgical referrals, and shortened hospital stays.

MALIGNANT PLEURAL EFFUSIONS

Malignant pleural effusions require both skill and judgment to effect an optimal palliation for the patient. The important point to recognize in these circumstances is that palliation of dyspnea secondary to fluid compression of the lung is the goal of treatment. In situations in which the patient is close to death, because of progression of the underlying malignancy or other organ dysfunction, it may be appropriate not to proceed with any further invasive maneuvers. If, however, the decision is made to intervene, several therapeutic options are available, including repeated ultrasound-guided thoracenteses, chest tube placement with chemical pleurodesis, and long-term indwelling pleural drain placement. An in-depth discussion of thoracentesis is presented elsewhere in this book.

THERAPEUTIC OPTIONS

Chest Tube With Chemical Pleurodesis

Palliation of a malignant pleural effusion can be achieved by chemical pleurodesis that attempts to obliterate the pleural space, thereby preventing reaccumulation of pleural fluid. This procedure can be accomplished either thoracoscopically with the instillation of a sclerosant on the pleural surfaces or at the bedside by injection of the sclerosant through a chest tube. In most cases, the pleurodesis agent of choice is talc. It produces an inflammatory reaction on the visceral and parietal pleural surfaces that leads to adhesion formation and pleural fusion when these surfaces are in direct apposition. In some instances, an idiosyncratic reaction can occur in which the entire lung becomes inflamed, leading to severe pneumonitis and respiratory distress. For this reason, synchronous bilateral chemical pleurodeses should never be attempted. Recovery after the initial one-sided pleurodesis should be ascertained before embarking on treating the contralateral side, if needed.

Chemical pleurodesis is optimally effective if the lung can completely reexpand, allowing apposition of the visceral and parietal pleural surfaces. Without this contact, as in the case of a "trapped lung," the therapy will be ineffective. Thoracoscopy not only allows evaluation of the ability of the lung to reexpand but also permits complete evacuation of the pleural effusion before instillation of the sclerosant.

Long-Term Indwelling Pleural Drain

With malignant pleural effusions in which the underlying lung is trapped because of tumor or pleural rind, chemical pleurodesis is not the optimal palliative option. If repeated thoracenteses are not wanted, a long-term indwelling pleural drain can be inserted for decompression and consequent relief of dyspnea secondary to recurrent malignant fluid accumulation. This device can be placed by a modified Seldinger technique using local anesthesia or at the time of thoracoscopy. The drain is tunneled under the skin for approximately 7 to 8 cm before entry into the pleural fluid collection. A Teflon cuff built into the drain is positioned just underneath the drain exit site from the skin. The tunneling and use of the Teflon cuff are measures that reduce the likelihood of infection and dislodgment.

These drains are constructed with a one-way valve device at the external end that allows patient self-management of a chronic pleural effusion by drainage on a regular basis, without the risk and inconvenience of repeated thoracenteses. Of interest, in our own experience, even in cases in which the lung has been "trapped" and does not initially fully reexpand, after 8 to 10 weeks of drainage by this method, a functional pleurodesis often can be achieved: The lung seems to gain some degree of reexpansion, along with drawing in of mediastinal, diaphragmatic, and other thoracic soft tissues around the previous fluid-containing cavity, such that no further fluid accumulates in the newly obliterated pleural space. When this occurs, the pleural drain can be removed in an outpatient setting. With use of local anesthesia, the Teflon cuff is freed up just beneath the skin, and the drainage tube is withdrawn.

Section 14
THORACIC SURGERY

Chapter 73
Preoperative Pulmonary Evaluation

Hilary Petersen • Peter Mazzone

Surgery can influence the patient's pulmonary function. Pulmonary complications of surgery are common, costly, and increase morbidity and mortality in both the near term and the long term. The preoperative assessment of lung function and optimization of the management of preexisting lung conditions can improve outcomes. This chapter discusses surgery-related changes in pulmonary physiology, the impact of common postoperative pulmonary complications, risk factors for these complications, and recommendations for preoperative pulmonary assessment and management, including those related to the evaluation of the lung resection candidate.

PULMONARY PHYSIOLOGY

During and after surgery, ventilation, ventilation-perfusion matching, and airway clearance are altered by many mechanisms. The mechanisms responsible and the degree of impairment are influenced by the type of surgery and the patient's underlying health. The following is a general description of potential physiologic changes related to surgery.

Ventilation The supine position leads to decreases in all lung volumes, except tidal volume, because of the loss of the mechanical advantage provided by gravity. General anesthesia can worsen the restrictive defect in part through respiratory muscle relaxation and a shift of the balancing recoil forces of the lung and chest wall. Lung and chest wall mechanics are altered by surgery, particularly sternotomy, thoracotomy, and upper abdominal procedures. Diaphragm dysfunction and basal atelectasis may persist long after surgery. The residual effects of anesthesia can impair ventilatory drive in the immediate postoperative period. Shallow breathing related to pain and the effects of opiate use also contribute. In combination, functional residual capacity (FRC) can fall up to 50% for as long as 1 week in high-risk patients undergoing high-risk procedures.

Ventilation-Perfusion Matching The reduction in FRC can be significant enough to result in atelectatic areas of the lung. Decreases in mucociliary clearance and the cough reflex secondary to anesthetic and opiate use and shallow breathing as a result of pain further contribute to the development of atelectasis. In atelectatic areas of the lung, ideal ventilation-perfusion matching shifts toward shunting where blood flow continues but ventilation is reduced or absent. This effect can be magnified by volatile anesthetic agents that influence hypoxic vasoconstriction. The end result of these changes is postoperative hypoxemia. Anemia and increased oxygen consumption may also contribute to observed oxygenation problems.

Airway Clearance Many of these mechanisms impair the postoperative patient's ability to clear their airways of mucus. Respiratory muscle dysfunction, atelectasis, pain, and medication use, resulting in a decreased cough reflex or decreased mucociliary clearance, are contributing factors.

POSTOPERATIVE PULMONARY COMPLICATIONS

The frequency of postoperative pulmonary complications (PPCs) varies with type of surgery, the patient's health, and the definition of the complication. Pulmonary complications of surgery are at least as common as cardiac complications and may result in prolonged hospital stays, increased morbidity and mortality, and increased costs (Table 73-1).

RISK FACTORS

The many risk factors for PPCs can be classified as patient or surgery related and assigned a simple rating based on the amount and quality of evidence available for support as a risk factor (Table 73-2).

Patient-Related Factors

In several studies, chronic obstructive pulmonary disease (COPD) has been found to double the risk of PPCs. The degree of risk is directly related to the severity of obstruction. One study of patients after upper abdominal surgery found that those with decreased breath sounds or other adventitious sounds (e.g., wheezing, rales) had a sixfold increased rate of PPCs.

In contrast, well-controlled *asthma* has not been found to be a risk factor for PPCs. A large retrospective analysis found that rates of bronchospasm, laryngospasm, and respiratory failure in patients with well-controlled asthma were comparable to healthy individuals. Those with poorly controlled asthma (e.g., more frequent albuterol use, recent emergency department visit for asthma) do have an increased risk for PPCs.

Pulmonary hypertension (PH), primary and secondary, may be associated with increased rates of PPCs and in-hospital mortality. In one study, 21% of patients with PH developed respiratory failure versus 3% in matched controls after noncardiac surgery.

A patient's general health may be assessed by using the American Society of Anesthesiologists (ASA) classification system (Table 73-3). Studies have shown a direct correlation between a higher ASA class and increased pulmonary complications. Patients with an ASA Class III or higher have a twofold to threefold increase in PPCs compared with those with ASA Class II or lower. Difficulty or inability to perform activities of daily living has also been linked to increased complications.

Table 73-1 **Postoperative Pulmonary Complications**

Surgery in General	Lung Resection Surgery
AECOPD*	Bronchopleural fistulas
Acute lung injury	Empyema
Aspiration events	Nerve injury (phrenic, recurrent laryngeal)
Atelectasis	Pleural effusions
Bronchitis and pneumonias	Pulmonary edema
Bronchospasm	Postpneumonectomy syndrome
Pulmonary embolism	Pulmonary torsion
Respiratory failure	

*Acute exacerbation of chronic obstructive pulmonary disease.

Obesity alone does not seem to increase the risk of PPCs. A wide review of gastric and general surgeries shows that obese and morbidly obese patients have the same risk for PPCs as nonobese patients. However, the presence of a common comorbidity in obese patients, *obstructive sleep apnea* (OSA), does confer increased risk. In a study of patients after hip or knee replacement, those with OSA had longer hospital stays or more frequent transfers to the intensive care unit (ICU). A more recent study found that those with five or more desaturation episodes during the night had greatly increased rates of PPCs. Therefore, patients should be asked about symptoms of OSA preoperatively.

Age is the most significant patient-related predictor for PPCs. Even after adjustment for comorbid conditions, increasing age is an independent risk factor for increased PPCs. Congestive heart failure (CHF) is also an independent risk factor and should be of particular concern in the elderly population.

Cigarette smokers have a moderately increased risk for PPCs, independent of comorbid lung conditions. Smokers have higher rates of wound infections, oxygen desaturation, laryngospasm, and increased coughing with anesthesia, all of which can lead to longer hospital stays and contribute to pulmonary complications. Quitting smoking before surgery lowers the rate of PPCs. Although early data suggested that quitting smoking close to surgery may increase the rate of PPCs, a recent meta-analysis shows this is not true. In general, the sooner a patient can quit smoking, the better it is for the patient, but smoking cessation should be encouraged at any time before surgery.

Surgery-Related Factors

The planned surgery and surgical site have an impact on risk for developing PPCs that is often greater than patient-related factors. Surgical site was the most important predictor for developing postoperative pneumonia and respiratory failure in a cohort of 160,000 U.S. military veterans undergoing major noncardiac surgery. Those undergoing abdominal aortic aneurysm (AAA) repair or thoracic surgery had the highest risk, followed by upper abdominal, neurovascular, and neck surgeries.

Duration of surgery, extent of anesthesia, and invasiveness of the surgery all influence the risk of developing PPCs. Patients undergoing emergency surgeries or surgeries lasting longer than 3 hours are at greater risk for PPCs. Surgeries requiring general anesthesia (GA) carry a greater risk for PPCs than with peripheral nerve blocks. There is questionable evidence about the relative risk of PPCs from surgeries requiring GA versus neuraxial blockade (spinal or epidural anesthesia). A previous large review of various surgeries reported increased rates of pneumonia, respiratory failure, and mortality in patients who received GA compared to those receiving neuraxial blockade. A more

Table 73-2 **Selected Risk Factors for Developing Postoperative Pulmonary Complications**

Risk Factor	Level of Prediction
Systemic Disease	
Asthma (well controlled)	Poor
Congestive heart failure	Good
Chronic obstructive pulmonary disease	Good
Diabetes mellitus	Fair
Human immunodeficiency virus infection	I
Obstructive sleep apnea	Good
Pulmonary hypertension	Fair
Signs and Symptoms	
Abnormal chest auscultation	Good
Arrhythmia	I
Functionally dependent	Good
Impaired mental status	Good
Poor exercise capacity	Fair

Box 73-1 Stop-Bang Questionnaire to Screen for Obstructive Sleep Apnea (OSA)

1. Snore: can the patient’s snoring be heard through a closed door?
2. Tired: is the patient hypersomnolent during the day?
3. Observed: have there been witnessed apneas?
4. Pressure: does the patient have hypertension?
5. Body mass index: greater than 35?
6. Age: older than 50?
7. Neck circumference: greater than 40 cm?
8. Gender: male?

Modified from Chung F et al: *Anesthesiology* 108:812–821, 2008.
The patient who answers “yes” to three or more of these eight questions is at high risk for OSA.

recent small review of orthopedic surgeries found equal rates of pneumonias in these two groups.

A study of patients undergoing AAA repair found increased rates of PPCs (16%) in open repair compared to endovascular repair (3%). Video-assisted surgeries have reduced PPC rates compared with open approaches. Limited data suggest that patients undergoing cardiothoracic robotic surgery have lower rates of PPCs than those not receiving robotic surgery.

SURGERY IN GENERAL

The most important part of a preoperative pulmonary evaluation is taking a complete history and performing a complete physical examination. For those without pulmonary disease or symptoms, or those with well-controlled chronic lung conditions, routine pulmonary function tests (PFTs) and chest imaging are not indicated.

During the office visit, symptoms or signs of an underlying or undiagnosed pulmonary condition may be discovered. If unexplained dyspnea, coughing, wheezing, other abnormal lung sounds, or chest pain is revealed, testing before an elective surgery may be indicated to identify their cause. Historical clues should aid in distinguishing cardiovascular dyspnea from pulmonary dyspnea and guide which tests should be performed. Pulmonary function testing will help to identify and quantitate physiologic impairment of lung function. If a cardiac etiology is suspected, an electrocardiogram, echocardiogram, brain natriuretic peptide level, and stress test may be performed. Other cardiac risk assessment is beyond the scope of this chapter.

Further testing, such as a chest radiograph, complete blood count, serum chemistries, and thyroid-stimulating hormone (TSH) level can help to determine the cause of cardiopulmonary symptoms and the need for additional testing. If the cause of dyspnea remains unclear, a cardiopulmonary exercise test may help determine its nature and quantify its severity. Additional chest imaging may also be required if a pulmonary cause of a concerning symptom is likely. Screening for PH is not recommended in the preoperative setting, particularly if respiratory symptoms are not present or are otherwise well explained. Since most, if not all, of the conditions causing dyspnea result in increased rates of PPCs, proper diagnosis and treatment optimization of that condition will improve patient outcomes.

During the history and physical examination, patients should be screened for OSA by asking about snoring, witnessed apneas, and daytime somnolence. Neck circumference and obesity should be noted. Validated questionnaires are available for identifying those at risk for OSA (Box 73-1). Evidence is limited on the usefulness of diagnosing OSA preoperatively with polysomnography, with decisions based on degree of clinical concern and urgency of the surgery.

Validated indices are available for predicting postoperative pneumonia and respiratory failure after major noncardiac surgery. The investigators from three select reviews assigned point values to corresponding risk factors, as summarized in Tables 73-4 and 73-5. Clinicians may find these tools helpful in identifying those at risk for postoperative pneumonia and respiratory failure and for selecting perioperative testing and respiratory care for those at high risk.

Table 73-5 Level of Risk Based on Point Value/Score

Risk Level*	Score from RRI	Predicted RF	Class†	Point Total from RFRI	Predicted RF	Point Total from PRI	Predicted Pneumonia
Low	<8	.2%	1	≤10	0.5%	0-15	0.24%
			2	11-19	2.2%	16-25	1.2%
Medium	8-12	1%	3	20-27	5%	26-40	4%
			4	28-40	11.6%	41-5	9.4%
High	>12	6.5%	5	>40	30.5%	>55	15.3%

See Table 73-4 for abbreviations.
RF, respiratory failure.
*Risk level for the RRI, updated respiratory risk index.
†Class indicates level of risk for the PRI and RFRI.

LUNG RESECTION SURGERY

For patients with non–small cell lung cancer (NSCLC), surgical resection with a lobectomy or pneumonectomy offers the best chance at cure. Approximately 20% of lung cancer patients are deemed to be surgical candidates. However, these resections are not without serious risk. The mortality for lobectomy is 2% to 3%, and for pneumonectomy, 4% to 6%. Overall, PPCs range from 20% to 30%. Meticulous patient selection by a multidisciplinary team for these procedures is imperative. The clinician must identify patients who have a poor prognosis without surgery, a low risk of operative mortality, and a high likelihood of tolerating well the reduced lung function after resection. Lung resection surgery is unique in that the reduction in lung function related to surgery does not occur only in the immediate postoperative period but rather persists. Thus, preoperative evaluation must consider not only PPCs but also the long-term effect of the loss of lung function on the patient's quality of life. The following general overview recognizes that decisions about lung resection need to be individualized, considering other treatment options, patient preferences, and comorbidities.

After a complete history and physical examination, the lung resection patient should undergo a thorough pulmonary assessment focusing on pulmonary reserve. All potential lung cancer resection patients should have spirometry performed. Patients with forced expiratory volume in 1 second (FEV_1) measurements above 2 L and 80% of predicted normal values, who are free of cardiopulmonary symptoms, should tolerate resection without the need for additional testing. For all others, a diffusion capacity (DLCO) measurement should be obtained, and *predicted postoperative* (ppo) *lung function* should be calculated.

Estimating postoperative lung function can help determine the risks related to lung resection surgery and identify patients likely to tolerate resection who may not qualify by other measures. An anatomic segment method or radionuclide quantitative perfusion imaging may be used for patients undergoing surgery up to a lobectomy; the latter is preferred for those likely to require a pneumonectomy.

To calculate ppo lung function with the *anatomic segment* method, the fraction of total lung segments that will remain after the resection is multiplied by the preoperative lung function value. The two equations typically used are based on pulmonary segment total (19) or subsegment total (42). Using the former, the predictions correlate well with a lobectomy but less so with a pneumonectomy. Overall, these calculations tend to underestimate actual postoperative lung function, particularly in those with baseline impairment of lung function.

Radionuclide quantitative perfusion studies estimate the relative function of the lung to be resected by quantifying perfusion to the portion of lung to be resected as a fraction of total lung perfusion. Postoperative lung function can be calculated similar to the anatomic segment methods. Radionuclide studies also consistently underestimate FEV_1 values in patients with lower baseline values. Although more accurate than segment methods for postpneumonectomy lung function prediction, the overall predictive value of quantitative perfusion studies is less than ideal.

Pulmonary Function Measures

Although clinicians cannot rely solely on pulmonary function measures to predict the risk of PPCs, perioperative mortality, or unacceptable levels of long-term dyspnea, the FEV_1 value does correlate with these outcomes. As a general rule, a preoperative FEV_1 value of 2 L or greater indicates that a patient without cardiopulmonary symptoms will tolerate a pneumonectomy, and with a value of 1.5 L or greater, a lobectomy. Because absolute values do not consider age, gender, or size, percent of predicted normal values are more useful. Values greater than 80% of predicted normal in those without symptoms support proceeding directly to resection without additional testing. As stated earlier, ppo values as a percentage of normal are also helpful in identifying patients capable of undergoing resection who might have otherwise been rejected based on absolute FEV_1 values.

Guidelines recommend that patients with FEV_1 values below the general parameters just listed and any symptomatic patient should have $ppoFEV_1$ values calculated. It is difficult and probably inappropriate to apply cutoff values for $ppoFEV_1$ to an individual patient. As expected, the lower the $ppoFEV_1$ value, the higher is the rate of complications or unacceptable outcomes. One study noted that no postoperative deaths occurred in patients with $ppoFEV_1$ greater than 40% after resection, whereas those with $ppoFEV_1$ less than 40% had a 50% chance of postoperative mortality. Another study found that all patients with a $ppoFEV_1$ of 30% or lower developed respiratory failure or died after resection.

The DLCO and ppoDLCO are also independent predictors for PPCs and mortality. The majority of patients undergoing lung resection should have DLCO measured. DLCO values may be low despite normal spirometry. As with FEV_1, one cutoff value for resection should not be applied equally to all patients. Lower values correlate with worse outcomes. Those with an absolute DLco of 60% predicted normal or lower had greater rates of postoperative respiratory failure and death in one study; ppoDLco values of 40% predicted normal or greater have been used as cutoffs in published guidelines. One study found that patients with ppoFEV_1 × ppoDLco (predicted postoperative product) of less than 1650 have a high mortality rate.

Exercise Testing

When questions remain after standard measures of lung function have been performed and ppo values have been calculated, measures of exercise capacity can be helpful. Cardiopulmonary exercise testing (CPET) with cycle ergometry has been used to assess a patient's fitness for resection. An individual's exercise capacity can be measured as the peak oxygen consumption (Vo_2 peak). Values greater than 20 ml/kg/min have been used to suggest the ability to tolerate pneumonectomy, 15 ml/kg/min for lobectomy, and less than 10 ml/kg/min for a high-risk group. Many studies have found this value to be an independent predictor for PPCs and mortality. Formal oxygen desaturation studies may be performed as well. A 4% oxygen desaturation is associated with increased PPCs, including respiratory failure, increased ICU stays, and home oxygen requirement. Stair climbing, a 6-minute walk test, and shuttle walking also provide measures of cardiopulmonary capacity that can assist with decisions about resectability.

Box 73-2 summarizes the American College of Chest Physicians (ACCP) recommendations for the preoperative pulmonary evaluation of the lung resection candidate. Figure 73-1 outlines the ACCP and European Respiratory Society and European Society of Thoracic Surgeons (ERS/ESTS) recommended steps to follow when assessing a patient's pulmonary fitness for lung resection. The differences in these guidelines highlight the lack of consensus in this area and the need to individualize patient decisions.

MANAGEMENT

Most patient-related and surgery-related risk factors are nonmodifiable. The following recommendations should be used in all patients regardless of their risk for PPCs.

Preoperative Measures For patients with airway obstruction (asthma, COPD) the use of inhaled bronchodilators and inhaled and systemic corticosteroids should be based on standard management and optimization of these conditions. It is not necessary to add these treatments in the perioperative setting if the patient's underlying condition is well controlled. There appears to be no risk of increased postoperative infections from a course of corticosteroids lasting less than 1 week. Antibiotics and cough expectorants should only be used in patients who are actively infected or are experiencing an acute exacerbation of COPD. All smokers should be strongly advised to quit smoking as soon as possible before surgery and should be provided with means available to help them quit. Breathing muscle exercises such as incentive spirometry, use of an inspiratory muscle trainer, deep-breathing exercises, or enrollment in a pulmonary rehabilitation program may be advised for those with underlying lung compromise undergoing high-risk surgery. Weight reduction for the obese patient is advised, particularly those with or at risk for OSA.

Patients at high risk for OSA should undergo a sleep study before their scheduled surgery if time permits. If OSA is proven, treatment with continuous positive airway pressure (CPAP) should begin as soon as possible. A recent study revealed that patients with newly diagnosed OSA had lower rates of respiratory failure if they had started CPAP therapy before surgery. Currently, data are insufficient to support postponing an elective surgery to optimize sleep apnea therapy.

Box 73-2 Summary of ACCP Guidelines for Lung Cancer Resection

- Patients should not be denied lung resection surgery based on age alone.
- All patients should undergo spirometry.
- An FEV_1 of 2 L or greater or 80% predicted in a patient without dyspnea or ILD may proceed to pneumonectomy. FEV_1 of 1.5 L or greater in a patient without dyspnea or ILD may proceed to lobectomy.
- If there is undue dyspnea or ILD evident, DLco is recommended.
- If DLco or FEV_1 is less than 80%, ppo lung function should performed.
- A ppoFEV_1 or ppoDLco less than 40% is consistent with increased PPCs and mortality after resection. Exercise testing is recommended.
- A postoperative predicted product of less than 1650 or a ppoFEV_1 of less than 30% indicates an increased risk for PPCs and death. These patients should be counseled on nonsurgical treatment options.
- In patients with a Vo_2 peak of less than 10 mL/kg/min or a Vo_2 peak of less than 15, with both ppoFEV_1 and ppoDLco less than 40% predicted, nonsurgical treatment options should be sought.
- Patients who walk less than 25 shuttles on two shuttle walks or less than one flight of stairs should be counseled on nonsurgical options.
- For those with a Paco_2 greater than 45 mm Hg or Sao_2 less than 90%, further testing should be performed prior to surgery.
- In lung cancer patients with upper lobe emphysema and FEV_1 and DLco greater than 20%, LVRS combined with resection may be considered.
- Smoking cessation is encouraged for all.

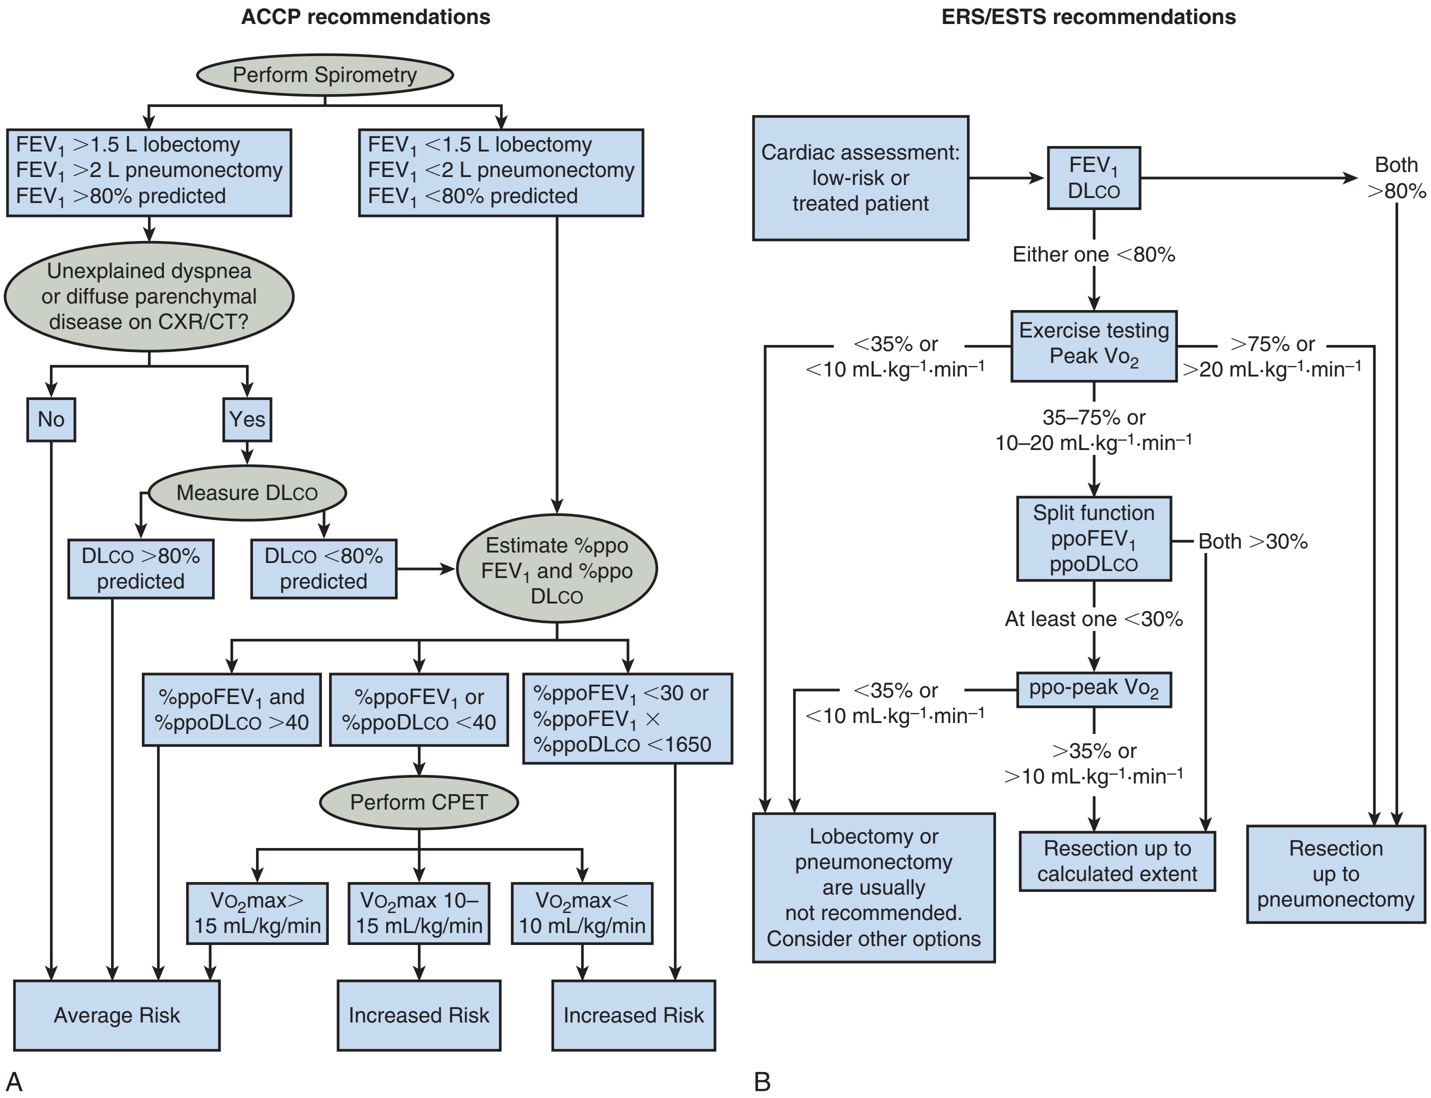
ACCP, American College of Chest Physicians; *FEV_1*, forced expiratory volume in 1 second; *DLco*, diffusion capacity; *ILD*, interstitial lung disease; *PPCs*, postoperative pulmonary complications; *Vo_2 peak*, peak oxygen consumption; *ppo*, predicted postoperative; *LVRS*, lung volume reduction surgery.

Surgical Management There is some evidence that the use of regional anesthesia over GA and the choice of a neuromuscular blocker other than pancuronium will reduce PPCs. These choices are rightfully influenced by the anesthesia needs of the procedure. Other operative measures to reduce PPCs include limited anesthesia and thoracotomy times, protective lung ventilation strategies, limited or intermittent hyperinflation to prevent atelectasis, control of secretions, and aspiration prevention measures.

Postoperative Measures After surgery, early ambulation, cough encouragement, mobilization of secretions, and adequate pain control will all help to decrease PPCs. The use of epidural analgesia during and immediately after surgery leads to improved outcomes in patients undergoing lung resection. Selective nasogastric decompression is recommended only for those with nausea or abdominal distention, to prevent



ACCP recommendations
Perform Spirometry
FEV$_1$ >1.5 L lobectomy

aspiration events. Incentive spirometry and deep-breathing maneuvers are recommended to decrease atelectasis and thereby decrease PPCs. For patients following lung resection surgery, pulmonary rehabilitation has been shown to assist with functional recovery.

CONCLUSION

Postoperative pulmonary complications are common and lend to significant morbidity and mortality as well as increased costs. The preoperative pulmonary evaluation should initially determine the level of risk for complications to provide guidance to the patient and surgeon. Many patient-related and surgery-related risk factors for PPCs are known. Validated clinical tools are available for assessing those at risk for pneumonia and respiratory failure, and evidence-based guidelines assist in assessment of the lung resection candidate. The other goals of the preoperative visit are to optimize the management of underlying diseases, have systems in place to minimize perioperative risks, and educate the patient about the techniques available, to ensure optimal conditions for an uneventful recovery.

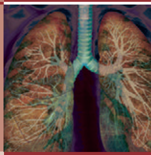
Section 14

THORACIC SURGERY



Chapter 74

Diagnostic Thoracic Surgical Procedures

Chadrick E. Denlinger • Stephen D. Cassivi • Mark S. Allen

Despite the ever-increasing sensitivity of noninvasive diagnostic modalities, especially in diagnostic imaging, diagnostic thoracic surgical procedures add critical information to the diagnostic workup of patients with diverse thoracic diseases. To provide definitive tissue diagnosis and to assess stage and resectability of chest tumors, the general thoracic surgeon is vital in the diagnostic evaluation of patients.

Common thoracic surgical procedures used for diagnosis include, in order of invasiveness, bronchoscopic, cervical, scalene, and supraclavicular lymph node, pleural, mediastinal, and pulmonary biopsy procedures that involve endoscopic, thoracoscopic, or open surgical approaches. There is a spectrum of invasiveness to these procedures, with exploratory thoracotomy representing the most invasive of these diagnostic techniques. The choice of procedure is guided by the particular clinical question to be answered, as well as specific patient characteristics and, at times, the individual surgeon's preference and experience. Overall, these procedures provide a high diagnostic yield, with low morbidity and mortality. Complications, although rare, do occasionally occur, and it is therefore incumbent on referring physicians to understand the nature of these procedures, the level of invasiveness, and the relative risk/benefit ratios.

PREOPERATIVE CONSIDERATIONS

Except for flexible bronchoscopy, which can be performed using topical anesthesia with minimal sedation, most diagnostic surgical interventions require general anesthesia. The physician first determines the appropriateness of the intervention, because some degree of operative risk is always present. A general contraindication to these procedures is excessive risk from comorbid conditions. The referring physician and ultimately the surgeon must assess the patient's overall medical status and ability to withstand the proposed procedure. Furthermore, a diagnostic surgical intervention, no matter how minimally invasive, is unnecessary and unwarranted if the findings of the procedure will not influence the treatment plan for the individual patient.

CLINICAL APPLICATION OF DIAGNOSTIC THORACIC PROCEDURES

The diagnostic thoracic surgical procedures discussed in this chapter have varied applications, with relative advantages and disadvantages (Table 74-1) and are typically used in the following three broad areas:

- Assessment of bronchogenic carcinoma
- Diagnosis of interstitial lung disease
- Sampling of indeterminate pleural, pulmonary, and mediastinal lesions

Bronchoscopy

In 1968, Ikeda introduced the first flexible bronchoscope, and over the decades, flexible bronchoscopy has largely supplanted rigid bronchoscopy for diagnostic procedures. Previously, rigid bronchoscopy was the only way to visualize and access the tracheobronchial tree directly. Now, however, the flexible bronchoscope provides access to a greater extent of the airway, can be performed with minimal sedation, and can be routinely performed in the intensive care unit (ICU) as well as the regular patient ward in many hospitals.

Flexible Bronchoscopy

As a diagnostic tool, flexible bronchoscopy offers a relatively noninvasive way to visualize and obtain tissue samples from the airways. The flexible characteristic allows access to subsegmental branches of the tracheobronchial tree. Although flexible bronchoscopy can be done through the endotracheal tube in an anesthetized and intubated patient, this procedure is usually performed with topical anesthesia and conscious sedation. Adjuncts to flexible bronchoscopy continue to evolve, further improving its diagnostic accuracy and utility.

Flexible bronchoscopy not only allows visualization of the tracheobronchial tree, but also provides access for obtaining tissue samples, such as washings, brushings, and bronchoalveolar lavage (BAL) fluid for cytologic and microbiologic analyses. Endobronchial and transbronchial biopsies can be obtained of the airway and lung tissue. In addition, transbronchial needle (Wang) biopsies of mediastinal lymph nodes can be performed through the flexible bronchoscope. This procedure requires a careful evaluation of preoperative images to help blindly pass a needle through the bronchus into the extraluminal lymph node of interest.

Endobronchial Ultrasound

The recent addition of endobronchial ultrasound (EBUS) technology has increased the sensitivity of transbronchial needle biopsies. This special bronchoscope includes the additional feature of a linear ultrasound probe at the end of the scope, which facilitates visualization of lymph nodes outside the airway. Color flow Doppler images also help differentiate lymph nodes from vascular structures. A working channel directs the passage of a transbronchial needle through the region imaged by the ultrasound, to biopsy discrete lymph nodes. EBUS is most frequently used for mediastinal lymph node staging of patients with known or presumed lung cancer. The diagnostic accuracy is similar to that of mediastinoscopy

Table 74-1 Diagnostic Thoracic Surgical Procedures

Procedure	Application	Advantages	Disadvantages
Rigid bronchoscopy	Diagnosis of carcinoma Clear airway obstruction	Removal of secretions/blood Large biopsy specimen may reveal submucosal tumor Opportunity to debulk inoperable tumors or excise benign lesions Assessment of carinal fixation	Poor view of secondary bronchial divisions
Cervical and scalene lymph node biopsy	Diagnosis of enlarged nodes	Safer technique than fine-needle aspiration (FNA) for deeper nodes Large tissue sample	Operative procedure; occasional technical difficulty
Mediastinoscopy	Diagnosis of middle mediastinal pathology (node/mass)	Direct access to mediastinal abnormality Much larger tissue sample than FNA	Operative field restricted to paratracheal and subcarinal areas
Mediastinotomy	Diagnosis of anterior mediastinal pathology (node/mass)	Reaches areas of anterior mediastinum inaccessible to mediastinoscopy Useful for subaortic node sampling May be safer to use than mediastinoscopy in patients who have superior vena cava obstruction Much larger tissue sample than in FNA	Operative field restricted to upper anterior mediastinum More complex operative procedure
Thoracoscopy	Pleural biopsy Biopsy of visceral pleura deposits	Can be effected through single puncture Visually directed biopsy	Limited to small biopsies Dependent on pleural cavity being free of adhesions
Video-assisted thoracoscopic/thoracic surgery (VATS)	Any ipsilateral biopsy or sampling procedure	Complementary to mediastinoscopy and mediastinotomy Excellent view and full operative intervention possible (e.g., wedge excision of pulmonary nodule, dissection of mediastinal mass)	Dependent on pleural cavity being free of adhesions Significant surgical expertise required

for this indication; two recent prospective studies show a similar diagnostic accuracy of EBUS and mediastinoscopy. Clearly, either procedure has great diagnostic value when performed by experienced clinicians.

Navigational Bronchoscopy

Previously, fluoroscopy was used to assist in directing the bronchoscope and biopsy forceps toward indeterminate peripheral lung lesions. The two-dimensional nature of fluoroscopy and the inability directly to "steer" the biopsy forceps were serious drawbacks of this modality. Navigational bronchoscopy using electromagnetic guidance was recently introduced to improve the yield of bronchoscopic lung biopsies. This technology depends on the construction of a virtual three-dimensional airway using CT images. An electromagnetic field created over the patient's chest helps to locate and direct a small endoscopic probe toward the lesion in airways beyond visualization with standard bronchoscopy. This technology can be used in combination with a small, radial ultrasound probe to help determine when the bronchoscope has reached the lesion of interest.

Currently the two most common applications of navigational bronchoscopy are to place fiducial markers or to obtain a tissue diagnosis of small lesions located in airways that are distal to the range of visualization. This technology is most useful for lung lesions within the inner third of the lung parenchyma. Lesions located closer to the periphery of the lung can be biopsied using computed tomography (CT)–guided techniques.

Rigid Bronchoscopy

Rigid bronchoscopy is mostly used for therapeutic airway interventions such as airway dilation, laser debridement, tumor debulking, placement of airway stents, or foreign body retrieval (Figure 74-1). The use of the rigid bronchoscope continues to be an important diagnostic tool in special circumstances, such as those requiring a better tactile sense when assessing for possible extrinsic tumor invasion of the airway, or when larger biopsies are sought. It is also indispensable when airway control is in question because of hemoptysis or tumor invasion.

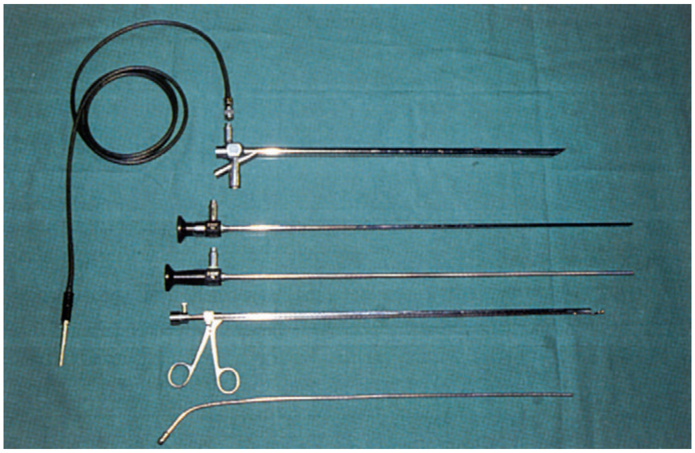


Figure 74-1 Rigid bronchoscopy equipment. *Top to bottom*, Bronchoscope with light cable, straight and right-angled surgical telescopes, biopsy forceps, suction cannula.

Rigid bronchoscopy requires general anesthesia with a muscle relaxant and specific ventilatory strategies. The options most often used include jet ventilation and continuous or intermittent insufflation. In patients with airway control as an overwhelming concern because of an obstructing airway lesion, muscle relaxants are avoided to maintain spontaneous breathing.

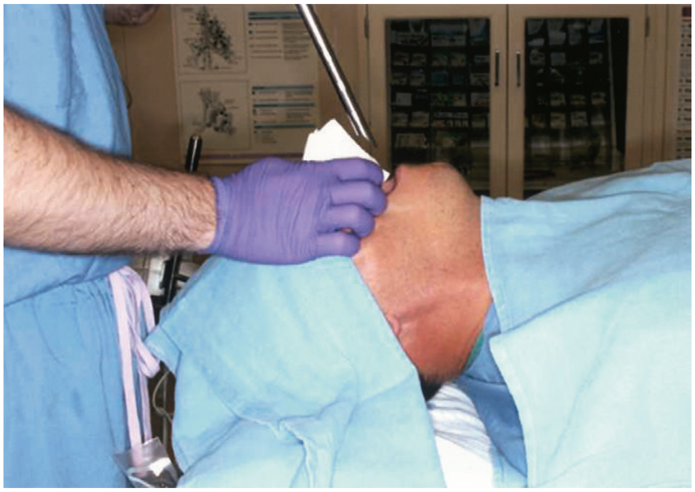

Figure 74-2 Positioning and insertion of rigid bronchoscope. The rigid bronchoscope is inserted with the bevel down while the patient is positioned supine with the neck extended.

Technique

In general, the size of the rigid bronchoscope used for adult men is 8 or 9 mm (outer diameter) and 7 or 8 mm for adult women. Smaller sizes are available for children or smaller adults.

After induction of anesthesia, the patient is positioned supine with the neck extended into the "sniffing" position. Right-handed surgeons use their left thumb to further protect the upper teeth and lips from injury and to serve as the fulcrum in positioning and supporting the bronchoscope throughout the procedure. Protection is also supplemented by use of a rubber tooth guard or saline-soaked gauze sponge. The patient's eyes are also shielded from inadvertent injury with padded covers for the duration of the procedure.

The bronchoscope is inserted through the right side of the patient's mouth with the bevel down (Figure 74-2). It is advanced toward the base of the tongue in the posterior oropharynx. The tip of the epiglottis is then identified by carefully elevating the tongue as the scope is brought more into a horizontal position. The scope is then advanced a short distance past the tip of the epiglottis. The protruding superior lip of the bronchoscope is then used to lift gently the tip of the epiglottis, allowing visualization of the vocal cords and laryngeal inlet. The surgeon will then rotate the bronchoscope 90 degrees along its long axis, placing the bevel in the anteroposterior plane to allow easy passage through the vocal cords. The bronchoscope can then be carefully advanced into the trachea under direct vision. To facilitate passage of the bronchoscope into the left or right main stem bronchus, the patient's head is turned to the contralateral side. Visualization of the segmental and subsegmental airways can be facilitated by insertion of a flexible bronchoscope through the lumen of the rigid bronchoscope.

Cervical, Scalene, and Supraclavicular Lymph Node Biopsy

Both bronchogenic and esophageal carcinoma may involve the lymph nodes in the cervical, scalene, and supraclavicular areas. Open biopsy of nonpalpable scalene lymph nodes is no longer a routine preoperative staging, and in fact, this procedure has become rare. Clinically positive or palpable nodes in this area are now accessed by fine-needle aspiration (FNA) directed by either CT or ultrasound imaging, if necessary. Patients who are thought to have lymphoma may require an open surgical biopsy to obtain a sample size adequate to assess for histologic architecture and sufficient tissue quantities for flow cytometry or additional studies required for a complete diagnosis.

A 3 to 4–cm–long skin crease incision is made at the level just above the insertion of the sternocleidomastoid muscle into the medial clavicle. Dissection can proceed between the clavicular and sternal heads of this muscle, or both can be retracted medially. The scalene fat pad lies on the anterior scalene muscle, lateral to the internal jugular vein, and usually receives its blood supply from the transverse cervical artery entering the fat pad inferiorly. This artery should be identified, ligated, and divided. Injury to the phrenic nerve is possible because of its location along the anterior surface of the anterior scalene muscle, deep to the fat pad. Other, rare but significant complications of open surgical lymph node biopsy include pneumothorax and thoracic duct injury with subsequent chylous fistula.

Cervical Mediastinoscopy

Cervical mediastinoscopy is a mainstay of lung cancer staging and was popularized in Europe by Carlens and in North America by Pearson in the 1960s. It is used not only for lung cancer staging but also to assess any lymphadenopathy in the pretracheal, paratracheal, and subcarinal areas. Lymph nodes that are accessible by the standard cervical approach are the highest: the upper and lower paratracheal and subcarinal levels as well as upper lymph nodes of the pulmonary hilum, or stations 1, 2, 4, 7, and 10 in the American Joint Committee on Cancer (AJCC) nomenclature. The "extended" cervical mediastinoscopy, introduced by Ginsberg, allows access to the aortopulmonary window and paraaortic lymph nodes (stations 5 and 6, respectively). More recently, level 5 and 6 lymph node stations are more often biopsied under direct vision by use of left thoracoscopy or anterior mediastinotomy.

Repeat mediastinoscopy, although technically possible, carries a higher risk of complications because of the loss of normal tissue planes to guide the usual dissection. Cervical mediastinoscopy can usually be performed as an outpatient procedure when done as an individual procedure. In many situations, mediastinoscopy is performed as a staged procedure that precedes a pulmonary resection. In experienced hands, mediastinoscopy provides substantial lymph node specimens, which are evaluated immediately by pathologists, who rule out lymph node metastases before the patient proceeds to an anatomic resection of the lung cancer.

Recently in Europe, more extensive procedures, referred to as *transcervical extended mediastinal lymphadenectomy* (TEMLA) and *video-assisted mediastinal lymphadenectomy* (VAMLA), have been proposed as alternatives to conventional cervical mediastinoscopy. These techniques are significantly more involved, with larger lymph node harvests accompanied by significant increases in the length of surgery (2-5 hours). Unfortunately, a recent trial of cervical mediastinoscopy versus TEMLA was prematurely halted before enough cases could be accrued for an adequately powered comparison of morbidity between these two staging procedures. Thus, we cannot accurately assess the risk of morbidity associated with the more invasive staging procedure.

Despite improvements in imaging of the mediastinum with CT imaging and positron emission tomography (PET), cervical mediastinoscopy remains the "gold standard" for preoperative staging of the mediastinum in lung cancer. Of special note is the low positive predictive value (PPV) of PET scans for staging

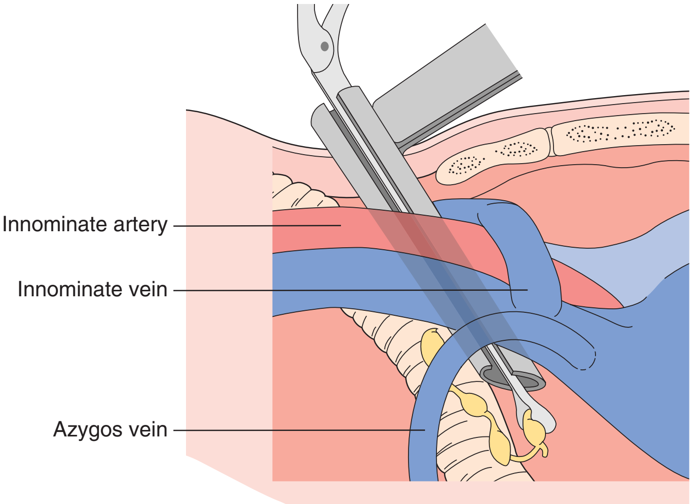

Figure 74-3 Path of cervical mediastinoscope.

the mediastinum in lung cancer. It is therefore imperative that a tissue diagnosis be obtained to document mediastinal metastases before surgical resection is denied. Cervical mediastinoscopy has a diagnostic accuracy of more than 98% in experienced centers and thus remains the mainstay of prethoracotomy mediastinal staging.

Technique

With the patient intubated and under general anesthesia, a bolster is placed under the shoulders to provide adequate neck extension for the procedure. A 2.5-cm transverse incision is made approximately 1 cm above the sternal notch. The pretracheal fascia is exposed by splitting the strap muscles in the midline, with right-angle retractors used to retract the thyroid gland superiorly if necessary. The pretracheal fascia is incised transversely and bluntly dissected off the anterior surface of the trachea with the index finger. This allows direct palpation of the vascular structures, including the aortic arch and innominate vessels, as well as any prominent lymphadenopathy. The mediastinoscope is introduced beneath the pretracheal fascia (Figure 74-3). Further blunt dissection can be done under direct vision using the tip of the mediastinoscopy sucker. Systematic dissection and biopsy of the different lymph node levels are then possible.

A spinal needle attached to a syringe can be used to aspirate and thus differentiate in equivocal circumstances between solid masses that can be biopsied and vascular structures that should be avoided. Most small bleeding can be controlled by judicious use of electrocautery or temporary gauze packing. Because of the risk of significant hemorrhage from injury to the many nearby vascular structures, the surgical staff should always be prepared for possible conversion to sternotomy or thoracotomy for definitive control of bleeding. Special care should also be taken when obtaining biopsy samples of lymph nodes in the left paratracheal area, because the left recurrent laryngeal nerve courses nearby and can be injured by aggressive biopsies or injudicious use of electrocautery.

Anterior Mediastinotomy

Anterior mediastinotomy, also known as the *Chamberlain procedure*, is a technique that provides access to the anterior mediastinum. It is typically used to sample lymph nodes in the aortopulmonary window and paraaortic lymph nodes (stations 5 and 6, respectively, in AJCC nomenclature). These nodal stations can also be accessed by extended cervical mediastinoscopy or left thoracoscopy. Although anterior mediastinotomy is somewhat more invasive than cervical mediastinoscopy, patients are usually discharged the day of surgery.

Although this technique is still performed, anterior mediastinotomy is being replaced by video-assisted thoracoscopic surgery (VATS; see next section) in many other centers. The advantage of an anterior mediastinotomy is that if the pleural space is not violated, the patient may go home the day of the procedure. However, the pleural space is often opened, and patient discomfort frequently leads to a brief hospital stay. VATS is becoming increasingly popular as a diagnostic procedure to assess the level 5 and level 6 mediastinal lymph nodes because of the superior visualization this technique provides and the additional ability to visualize the entire thoracic cavity.

Technique

A 3 to 4–cm transverse incision is usually made in the second interspace, just lateral to the lateral sternal border for anterior mediastinotomy. The pectoral muscle can usually be split in the line of its fibers without cutting through muscle. The intercostal muscle is then incised along the upper edge of the second costal cartilage. The internal mammary vessels, located medially, can usually be avoided and preserved. The mediastinal pleura are bluntly pushed laterally to avoid entry into the pleural space. The mediastinoscope is introduced to permit optimal lighting and visualization and obtain appropriate biopsies.

Occasionally, the mediastinal pleura are breached. A chest tube is generally not required if the lung parenchyma has not been damaged. At the end of the procedure, a small catheter can be inserted into the pleural space through the mediastinotomy. The tube is pulled out once the overlying muscular tissues have been almost closed, with the anesthesiologist providing sustained positive-pressure ventilation to evacuate any residual intrapleural air.

Video-Assisted Thoracoscopic Surgery

Minimally invasive access to the lung, pleural space, and mediastinum can be obtained by video-assisted thoracoscopic (thoracic) surgery. VATS is useful in the diagnosis of pleural pathology such as diffuse or focal thickening because of mesothelioma, pleural metastases, asbestos-related plaques, or benign inflammatory pleuritis. Thoracoscopy can also assist in the diagnosis and treatment of pleural fluid collections. In the staging of lung and esophageal cancer, thoracoscopy can provide access, in a minimally invasive way, to the paratracheal, prevascular, aortopulmonary window, paraaortic, subcarinal, paraesophageal, and inferior pulmonary ligament lymph node groups (stations 2 to 9, respectively, in AJCC nomenclature). Tumor invasion of local structures and overall resectability can also be assessed. Thoracoscopy is also used to obtain biopsies of lung tissue to assess discrete nodules or diffuse lung disease.

Thoracoscopy is most effectively done with single-lung ventilation of the contralateral side using a double-lumen endotracheal tube or bronchial blocker. This allows collapse of the lung on the operated side, permitting adequate visualization and maneuverability within the pleural space. Dense pleural adhesions are therefore a contraindication for effective thoracoscopy, as is the inability to tolerate single-lung ventilation.

Although thoracoscopy is a form of minimally invasive surgery, it remains a high-risk procedure when performed in high-risk patients. Of particular note are patients with interstitial lung disease (ILD) requiring lung biopsy to tailor treatment options. These patients usually have severe respiratory compromise before VATS and may already be receiving mechanical ventilation, with a significant proportion having elevated pulmonary artery pressure. Patients with pulmonary hypertension do not tolerate single-lung ventilation well because of their inability to perfuse the ventilated lung preferentially. Therefore, a significant amount of blood is shunted through the nonventilated lung, and the patient experiences significant hypoxemia while attempting single-lung ventilation. In the Mayo Clinic experience, patients with ILD undergoing thoracoscopic lung biopsy had an operative mortality of just under 6%.

Technique

Thoracoscopy is performed by use of single-lung ventilation of the contralateral side. The patient is positioned in the lateral position similar to the positioning used for a posterolateral thoracotomy. When VATS is done for drainage and evaluation of a pleural effusion, a single 1-cm port is usually sufficient. It is placed in the sixth or seventh interspace in the anterior axillary line. Through this port, the camera and a thin suction tip or biopsy forceps can be introduced and maneuvered. For most other applications, one or two additional 1-cm ports are required, usually positioned separately along the fourth or fifth interspace, in the line of a potential posterolateral thoracotomy (Figure 74-4). In this way, conversion to thoracotomy simply requires extending the incision between these two upper port sites. The anterior port can be converted to a 5-cm to 7-cm "access" port for removal of a lobectomy specimen, if the procedure requires conversion to a VATS lobectomy, in the case of a biopsied lung nodule found to be an invasive primary lung cancer.

Whereas biopsy for diagnosis of ILD requires only defining several areas of representative pathology, *wedge resection* of an indeterminate pulmonary nodule first necessitates precise localization of the lesion. This is usually done with the surgeon's finger introduced through one of the thoracoscopy incisions (Figure 74-5). It is clearly easier to locate larger and peripherally located lesions. Smaller or deeper lesions may not be accessible and may require conversion to open thoracotomy. In general, a pulmonary nodule can be palpated during a VATS exploration if the diameter of the lesion is greater than the depth of lung tissue through which it is felt. Recent experience has been initially promising with radiotracer guidance (technetium 99m) to locate small pulmonary lesions not otherwise discernible thoracoscopically.

Once the area to be biopsied has been located, an endoscopic stapling device can be inserted through a thoracoport and used to perform a wedge resection (Figure 74-6). Once the specimen has been resected, it should be removed from the pleural cavity within an endoscopic specimen retrieval bag to avoid port site contamination. A more economical alternative is to use a surgical glove introduced through one of the port sites and held open with two Kelly clamps.

The biopsy specimen should be processed initially on a sterile back table in the operating room. In the case of diffuse lung infiltrates, the staple line can be excised and used for microbiology culture testing, whereas the remainder of the specimen is sent to pathology for histologic evaluation. When an indeterminate lung nodule is excised, a small portion

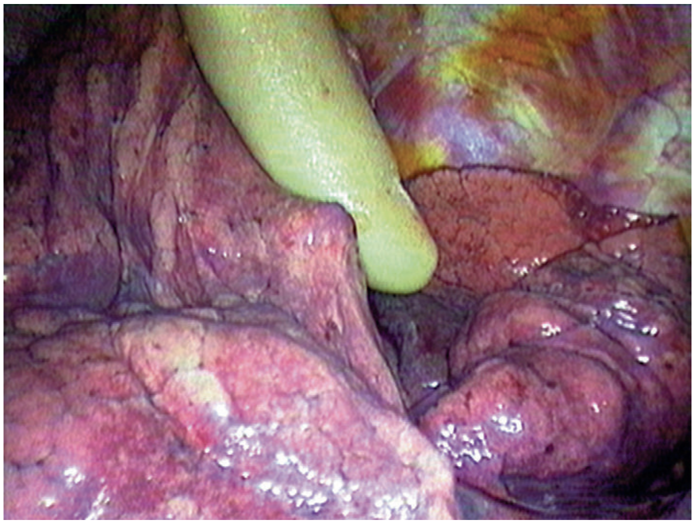

Figure 74-5 Palpation of intrapulmonary nodule during thoracoscopic surgery.

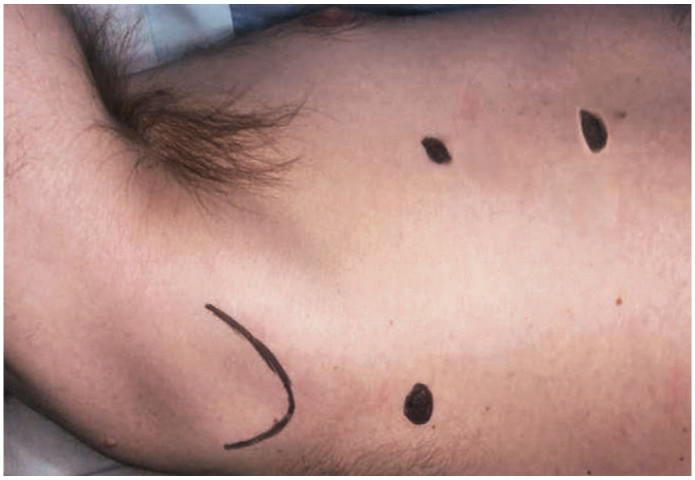

Figure 74-4 Location of thoracoscopic port sites. One port is placed at the seventh interspace in the anterior axillary line. Further ports may be required and are usually placed along the line of a potential posterolateral thoracotomy incision at the level of the fifth interspace.

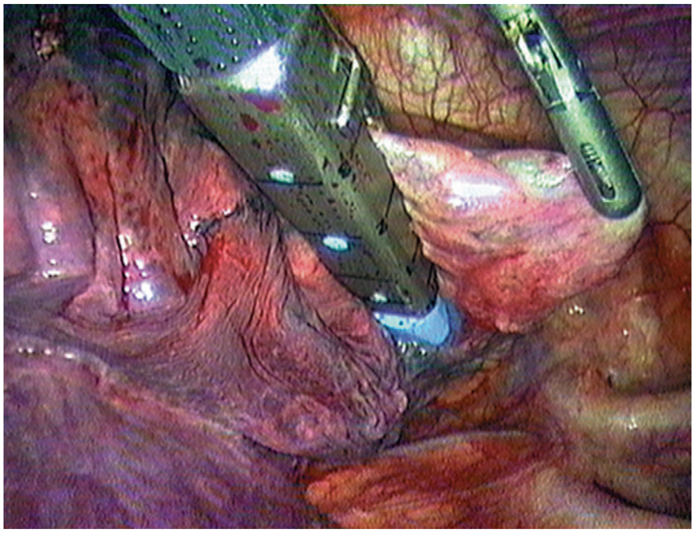

Figure 74-6 Use of endoscopic stapler during video-assisted thoracoscopic surgery (VATS).

should be kept for microbiology cultures, should the evaluation of the rest of the nodule suggest a nonmalignant diagnosis.

After all biopsies have been taken, the pleural cavity should be reassessed for any bleeding or other injury. Special attention should be paid to the staple lines and port sites. Once hemostasis is ascertained, a single, 28-Fr chest tube is introduced through the initial thoracoport in the seventh interspace anteriorly. It is guided posteriorly, with care taken to avoid placement within the fissure. Barring a significant air leak, this tube can usually be removed in 12 to 24 hours and the patient discharged the day after surgery.

Open Thoracotomy

Although a common procedure for thoracic surgeons, open thoracotomy is at the far end of the spectrum of patient morbidity for thoracic surgical procedures performed only for diagnostic purposes and therefore usually the *least* preferred option. However, this procedure is indicated and serves as the best diagnostic modality available in patients who, because of a fused pleural space or the inability to withstand single-lung ventilation, cannot safely undergo thoracoscopy. Frequently, patients referred for open-lung biopsy are critically ill and have significant pulmonary compromise, often requiring mechanical ventilatory assistance. Although open-lung biopsy is generally an accurate diagnostic tool, most studies do not show a survival benefit in critically ill patients with diffuse lung disease, even when a biopsy directs a change in therapy. Special care should be taken to assess the risk of such a procedure and its likely diagnostic yield in the specific patient's situation.

Technique

Usually, the patient undergoing thoracotomy for diagnostic purposes is placed in the lateral position, with both arms flexed forward at the shoulder. The incision is made transversely, one to two fingerbreadths beneath the scapular tip. This provides access to the fourth, fifth, or sixth interspace. Alternately, the patient is positioned supine, and an anterolateral thoracotomy is performed just beneath the mammary fold in the fourth or fifth interspace. As with the thoracoscopic approach, pulmonary resection is usually performed with the assistance of surgical stapling devices. At the end of the procedure, before closing the wound, a single, 28-Fr chest tube is inserted through a separate incision in an interspace beneath the main thoracotomy incision. Guided into the pleural space and positioned posteriorly, this tube will remain until drainage of air or fluid ceases.

CONCLUSION

A spectrum of surgical procedures is available to assist in diagnosis of thoracic diseases. The choice of the optimal diagnostic approach is based on individual patient characteristics, the specific diagnostic dilemma, and the surgeon's preferences and experience. It is essential to have a thorough understanding of the particular clinical situation, the advantages and disadvantages of the procedural alternatives, and the therapeutic implications of each possible diagnostic finding. This will allow the performing clinician to provide the most useful diagnostic answer with the least risk to the patient. Only then will the clinician avoid being more than a mere technician.

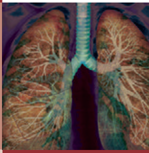
THORACIC SURGERY



Chapter 75

Lung Transplantation

Pamela J. McShane • Luis G. Ruiz • Edward R. Garrity, Jr.

Pulmonary transplantation has become an effective and reliable means to improve survival and quality of life in carefully selected patients with end-stage pulmonary disease. The current success in transplantation is attributed to appropriate referral, early selection, careful evaluation, and improving management of lung allograft donors and recipients. The multidisciplinary approach (**Figure 75-1**), together with meticulous clinical care of each transplant candidate (including understanding of the underlying disease state and optimization of psychosocial status), is of the utmost importance. The concurrent advances in surgical techniques, combined immunosuppressive regimens, surveillance for rejection and institution of prophylaxis, and early treatment of infection have resulted in the excellent survival rates and quality of life witnessed today.

The major challenges of preventing graft rejection and infection continue to impede progress. Lung transplant recipients face higher mortality rates and more frequent loss of graft function than other solid organ transplant recipients. Imbalance between organ supply and demand stresses the allocation system.

HISTORY

The pioneering experiments of numerous researchers who attempted to transplant heart, lung, and combined heart-lung blocks in different animal models laid the foundation for thoracic organ transplantation. In the 1950s, successful canine experiments performed by Demikhov, Metras, Hardin, and Kittle made lung transplantation a reality. In 1963, Dr. James Hardy and his team at the University of Mississippi Medical Center performed the first successful human lung homotransplantation. The recipient was a man with severe emphysema and a nonresectable left-sided lung cancer. His donor had recently died from a massive myocardial infarction. As with most early lung transplant procedures, the allograft was harvested from a non–heart-beating donor, an approach that is currently reemerging as a partial solution for the organ shortage. Immediately after the operation, which lasted less than 3 hours, the patient's oxygen saturation improved, providing the first evidence of adequate allograft function. Unfortunately, the initial success was met with failure, because the recipient died 18 days later from renal failure. Nearly 45 different transplantation attempts followed over the next 20 years. In almost all cases, failure seemed to stem from a lack of adequate bronchial perfusion to the anastomosed airways, which led to necrosis, dehiscence, and infection, in concert with lack of medications adequate to prevent acute rejection.

In the early 1980s, lung transplantation entered a new era. Dr. Bruce Reitz and the Stanford transplant group were able to achieve long-term survival with their series of combined heart-lung transplantations. Part of their success was attributed to the lack of bronchial ischemia as a result of performing the combined heart-lung approach that left the coronary circulation intact to provide collateral blood flow to the main airways after the bronchial artery had been ligated. The concurrent use of cyclosporine, the first effective T cell suppressor drug approved for use in solid organ transplantation in the United States, helped ameliorate acute rejection episodes. Dr. Joel Cooper and the Toronto transplant group also documented success with single-lung transplants and then with en bloc bilateral lung transplants. Improved bronchial healing was achieved with omentopexy (i.e., wrapping omentum around the anastomosis to facilitate neovascularization). Omentopexy has been replaced, first by the telescoping bronchial anastomosis technique first described by Dr. Frank Veith in 1969, and then by the end-to-end technique. In the late 1980s, the bilateral sequential single-lung transplant technique, as developed by the Toronto and San Antonio programs, became the procedure of choice for double-lung transplantation.

Over the next 2 decades, the state of lung transplantation grew sporadically, but quickly, and has now stabilized. The most recent reports from multiple lung transplant centers throughout the world indicate that bilateral and single-lung transplants continue to account for most procedures performed. Heart-lung transplants are now rare and reserved primarily for those patients with the Eisenmenger anomaly or severe primary pulmonary hypertension.

CURRENT TRENDS IN LUNG TRANSPLANTATION

In the United States, the United Network for Organ Sharing (UNOS) has been operating the Organ Procurement and Transplantation Network (OPTN) since 1984. The International Society for Heart and Lung Transplantation (ISHLT), in collaboration with UNOS, created a worldwide registry of all heart and heart-lung transplant procedures in 1982. The Twenty-seventh Report documents that more than 32,000 lung transplant procedures have been performed since that time, with 2769 lung transplant procedures done in 2008 by 158 transplant centers worldwide. Most current transplant procedures involve bilateral sequential or double-lung transplants (**Figure 75-2**). Seventy-three heart-lung transplant procedures were done during that same year.

Although the number of lung transplant procedures has increased substantially in the past 2 decades, the leading indications for lung transplantation remain relatively unchanged: chronic obstructive pulmonary disease (COPD), idiopathic pulmonary fibrosis (IPF), cystic fibrosis (CF), α_1-antitrypsin

(A1A) deficiency with emphysema, and pulmonary arterial hypertension (PAH) (**Figure 75-3**). The type of transplant a patient receives is dictated in part by the recipient's underlying disease: Recipients with COPD and IPF tend to receive single-lung as often as double-lung transplants, whereas those with CF and PAH almost always receive bilateral lung transplants (**Figure 75-4**). Over the past several years, a trend toward performing double-lung transplants and transplanting older people in the 55 to 65 age range has emerged (**Figure 75-5**).

In March 2011, UNOS estimated a total of 1790 patients on the active waiting list in the United States. The median waiting time for those listed in the period 2003 to 2004 was approximately 2 years. The most recent waiting list time is not yet known, but after the implementation of the Lung Allocation Score (LAS), median waiting times seem to have shortened. Twenty-five percent of patients undergo transplantation

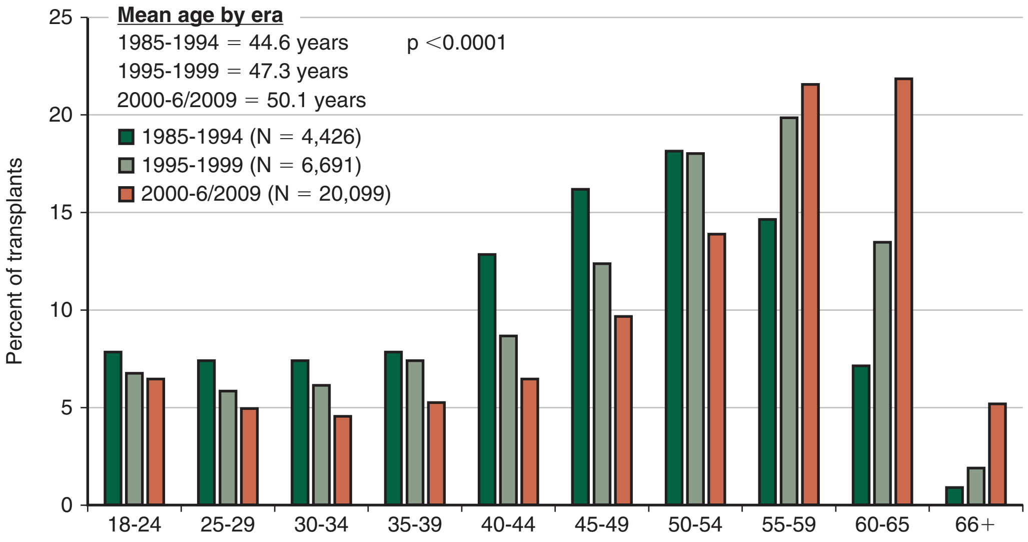

Figure 75-5 Age distribution of adult lung transplant recipients by era.

within 3 months. Today, donors selected for lung donation are older, with a mean age of 38 years, and more donors older than the age of 59 are now accepted.

SURVIVAL

Achieving successful outcomes and maximal survival in the lung transplant population starts with the proper selection of transplant candidates. This entails an understanding of the natural history of the recipient's lung disease and the projected survival with optimal medical and surgical therapy. Identifying potential candidates must be based on their current quality of life and the potential for improvement with and without transplantation. The median survival for lung transplant recipients has improved dramatically over the past several years. Transplant procedures performed from 2000 to 2004 were associated with a median survival of 5 years, significantly higher than for previous years (Figure 75-6). The survival curve is not linear, however, because approximately 20% of all recipients die in the first year after transplantation, with most occurring in the first 90 days. After this rapid decline, survival then stabilizes and follows a more linear trajectory, with an estimated 6% mortality rate per year. First-year mortality is attributable to postoperative graft complications, infection, cardiac failure, rejection, and early toxicity from immunosuppressive medications (Figure 75-7).

Several independent factors also seem to affect survival, including older age, higher body mass index (BMI), severe pulmonary hypertension, the type of transplant procedure performed, and the recipient's native pulmonary disease. In recipients older than 65, the expected 5-year median survival is 3.4 years, considerably lower than the overall average 5-year median survival. This is one reason why age older than 65 is considered to be a relative contraindication (Table 75-1).

Bilateral lung transplantation (BLTx) is associated with a median survival of 5.6 years, compared with 4.3 years for single lung transplantation (SLTx) (Figure 75-8). Although heart-lung transplantation (HLTx) is associated with the lowest median survival rates of approximately 3 years, HLTx procedures also are the least commonly performed. Although it seems that

Modified from Orens JB, Estenne M, Arcasoy SM, et al: International guidelines for the selection of lung transplant candidates: 2006 update—a consensus report from the Pulmonary Scientific Council of the International Society of Heart and Lung Transplantation, *J Heart Lung Transplant* 25:745–755, 2006.

bilateral lung transplant recipients have a better survival, specifically in the COPD group, this finding is controversial, because the observation is retrospective and uncontrolled. One contributing factor may be that older patients tend to receive single-lung transplants, whereas younger patients receive bilateral lung transplants. The highest survival rates are seen in patients with COPD and CF. The lowest survival rates are seen in patients with IPF and PAH, with a relative risk of death exceeding 2.0 in the first year after transplantation (Figure 75-9).

GENERAL SELECTION CRITERIA

The International Consensus Guidelines for referral and selection of transplant candidates were published in 1998 as a joint effort from the American Society of Transplant Physicians,

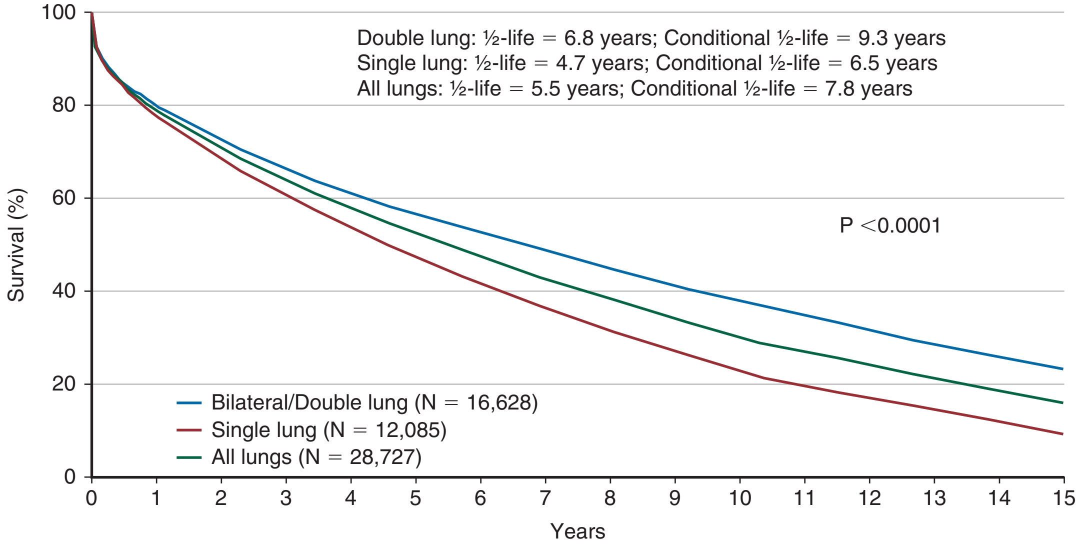

Figure 75-8 Kaplan-Meier survival by procedure type for adult lung transplants performed between January 1994 and June 2009. the American Thoracic Society, the European Respiratory Society, and the International Society for Heart and Lung Transplantation, to facilitate the appropriate timing of referral and proper selection of candidates most likely to benefit from transplantation while ensuring a fair allocation of limited organs. These guidelines were updated in 2006 (Table 75-2). In all instances, selected patients with end-stage pulmonary disease should have declining and irreversible lung function despite optimal medical and surgical management. To justify the risk of transplantation, patients should have an estimated survival of less than 2 years.

Two issues regarding this 2-year survival recommendation merit clarification. First, unique to lung transplantation, survival will vary as a function of the recipient's primary disease. Within the first 2 years, survival rates stabilize and allow a more accurate prediction of subsequent survival. Second, the average waiting time for a transplant is close to 2 years. If transplanted prematurely, patients may lower their survival benefit and keep more terminal candidates from transplantation. Therefore, the most current projected prognosis of lung diseases, the average time on the waiting list, and the median survival after lung transplantation should be considered in determining timing for selection. The new Lung Allocation System in the United States also affects this planning, in that the time to transplantation seems to be shorter, but a median waiting time for patients has not yet been determined. In essence, this is a moving target that will take more time to define.

The typical age for HLTx is younger than 55 years, BLTx younger than 60, and SLTx younger than 65. Medical conditions associated with damage to other organs are considered absolute contraindications. The exception is in rare selected cases with potential for combined heart-lung, lung-kidney, or lung-liver transplantation. For this reason, diagnosis and management of hypertension, diabetes mellitus, gastroesophageal reflux, peptic

Modified from Orens JB, Estenne M, Arcasoy SM, et al: International guidelines for the selection of lung transplant candidates: 2006 update—a consensus report from the Pulmonary Scientific Council of the International Society of Heart and Lung Transplantation, *J Heart Lung Transplant* 25:745–755, 2006.

ulcer disease, and osteoporosis should be aggressive. Renal impairment is considered an absolute contraindication to transplantation if the creatinine clearance is less than 50 mg/mL/minute.

Cancer screening includes mammography, Papanicolaou smear, PSA assay for prostate, and colonoscopy as medically indicated. A history of cancer is not an absolute contraindication. Eligibility is determined by cancer type and requires documentation of cure without evidence of recurrence or metastasis. In patients with a history of lymphoma, breast, colon, renal, or prostate cancer, a 5-year cancer-free period is required, because these cancers tend to have a longer recurrence period. Less aggressive skin cancers, such as squamous and basal cell, should be in remission for longer than 2 years.

Osteopenia and osteoporosis should be sought with bone densitometry measurements. Bone demineralization should be treated before transplantation by proper nutrition, calcium supplementation, vitamin D, bisphosphonates, and/or hormone replacement. Medications that increase bone resorption should be discontinued. Symptomatic osteoporosis is considered a relative contraindication. The future need for chronic steroid and immunosuppressive therapies will worsen bone loss. This can result in impaired ambulation and suboptimal rehabilitation and limit posttransplantation quality of life.

Nutritional state also affects outcome and postoperative rehabilitation. Candidates should weigh more than 70% but less than 130% of their ideal body weight. Generally speaking, a BMI between 18 and 30 kg/m^2 is acceptable. For patients whose BMI or weight is outside of these limits, a weight gain or weight loss program should be instituted with subsequent reevaluation for candidacy. Percutaneous enteral feeding may be necessary to achieve the desired nutritional goal. Total parenteral nutrition is an option but is not recommended with any enthusiasm because of the attendant risk of infection.

Dependence on tobacco, alcohol, or drugs must be treated, and patients should be substance-free for longer than 6 months. Disabling psychoaffective disorders, noncompliance, and lack of proper social support are relative contraindications. In our institution, social workers assess the support systems to maximize compliance with postoperative interventions and medications. Financial issues, including supplemental aid from hospital programs, insurance companies, and government agencies, as well as family and community support, must be explored preoperatively.

Invasive mechanical ventilation is considered a relative contraindication. Retrospective analyses suggest that acutely ventilated patients have a very high risk of perioperative complications, with a mortality rate surpassing 50%. On the other hand, chronically ventilated patients without other contraindications may have acceptable survival rates if they are otherwise good candidates.

Musculoskeletal disease that limits ambulation and breathing is an absolute contraindication. Less severe disease is acceptable if the recipient can undergo adequate rehabilitation and have a meaningful quality of life after transplantation. Restrictive anatomic deformities of the thorax and skeleton are considered relative contraindications.

Chronic active infection with human immunodeficiency virus (HIV), hepatitis B, and hepatitis C are considered absolute contraindications. Recipients colonized with multidrug-resistant *Burkholderia cepacia* complex (BCC) exhibit an extremely high rate of mortality and graft failure. BCC often is found in patients with CF, and many centers consider this to be an absolute contraindication. Survival in recipients with multidrug-resistant *Pseudomonas aeruginosa* is similar to that in noncolonized patients. Previously treated infection with *Mycobacterium tuberculosis* is not a contraindication. Treatment of various pulmonary infections may be started preoperatively in some patients in an attempt to decrease the pathogen burden. In others, postoperative prophylaxis may be instituted for those who are deemed to be at high risk for infection or reactivation (e.g., with *Aspergillus* colonization). A higher risk of infection still exists in colonized recipients who receive bilateral lung transplants, because many colonizing bacteria and fungi may spill down into the lung from sinuses, nasopharynx, and trachea.

DISEASE-SPECIFIC CONSIDERATIONS FOR REFERRAL AND SELECTION

Chronic Obstructive Pulmonary Disease

Patients with COPD (i.e., emphysema, chronic bronchitis, and obliterative bronchiolitis) have the highest survival rates after transplantation (emphysema related to A1A deficiency is considered a separate condition).

Survival benefit has not been documented in patients with COPD, even though transplantation confers substantial improvement in functional capacity and quality of life. One potential explanation for this discrepancy is that the forced expiratory volume in 1 second (FEV_1) may not be as reliable a referral parameter as, for example, the BODE index (determined by scoring for *b*ody mass index, airway *o*bstruction, *d*yspnea, and *e*xercise capacity) (Table 75-3). Patients with a BODE index between 7 and 10 should be selected for transplantation. Other criteria for selecting candidates with COPD include severe worsening of pulmonary function, shorter 6-minute walking distance capacity (less than 100 yards), weight loss (BMI less than 20 kg/m^2), need for hospital admission (to the intensive care unit [ICU] in particular), and radiographically homogeneous emphysema. More severely affected patients will show chronic hypoventilation (i.e., $PaCO_2$ greater than 55 mm Hg and evidence of pulmonary hypertension despite oxygen therapy). All patients with COPD should be referred for pulmonary rehabilitation and treated with oxygen therapy, and use of an alternative approach such as lung volume reduction surgery should be either documented as not a viable option or proved to be ineffective.

Table 75-3 **BODE Index Computation**

	Points			
Variable	**0**	**1**	**2**	**3**
Airflow obstruction (FEV_1 % predicted)	≥65	50-64	36-49	≤35
6-minute walk test (distance in meters)	≥350	250-349	150-249	≤149
MMRC dyspnea scale (range 0-4)	0-1	2	3	4
Body mass index	>21	≤21		

BODE, body mass index, airway obstruction, dyspnea, exercise capacity; *FEV_1*, forced expiratory volume in 1 second; *MMRC*, Modified Medical Research Council.

Modified from Celli BR, Cote CG, Marin JM, et al: The body-mass index, airflow obstruction, dyspnea, and exercise capacity index in chronic obstructive pulmonary disease, *N Engl J Med* 350:1005–1012, 2004.

Pulmonary Fibrosis

IPF is the most progressive of the fibrotic diseases and is defined by the histologic diagnosis of usual interstitial pneumonitis (UIP). No treatment for IPF is known to be effective; accordingly, patients can only be supported with supplemental oxygen, pulmonary rehabilitation, and close clinical surveillance. Prompt referral of appropriate candidates for lung transplantation is essential, because it is the only measure that will prolong survival in those at highest risk for death. IPF has a median survival of 3 years from the time of diagnosis, consistent with the 30% mortality rate documented for patients with IPF awaiting transplantation. Lung function parameters are used to decide when patients should be referred (i.e., a forced vital capacity [FVC] less than 60% to 70% of predicted, a diffusion capacity for carbon monoxide [DLCO] less than 50% to 60% of predicted). Many, however, feel that these cutoffs are too low, because they underestimate mortality. Other variables indicating higher mortality rates include hypoxia developing during a 6-minute walk test (pulse oximetry less than 88%), a resting PaO_2 level less than 50 mm Hg measured in room air, classic radiologic or histologic features of UIP, and a decline in lung function within 6 months of the initial diagnosis.

Other causes of pulmonary fibrosis tend to be associated with a better prognosis. Nonspecific interstitial pneumonia (NSIP), particularly the cellular variant of NSIP, has a 5-year survival rate of 75%. Other fibrotic diseases that may lead to lung transplantation include sarcoidosis, scleroderma, rheumatoid arthritis, mixed connective tissue disorders, asbestosis, histiocytosis X, and lymphangioleiomyomatosis. In general, the same criteria for referral should be used with all of these, because more disease-specific criteria have not yet been developed.

Cystic Fibrosis

Patients with CF frequently have multiorgan involvement and comorbid conditions, including malnutrition, chronic infections of the upper respiratory tract, and colonization with resistant pathogens. Current referral guidelines are inadequate, because good prognostic models for survival in CF do not exist, but patients with an FEV_1 less than 30% predicted or with declining pulmonary function should be referred early. This consideration is most important in female patients younger than 20 years of age, who seem to have a worse prognosis. Severity of disease also may be indicated by an increase in the frequency of hospital admissions, specifically, if ICU care is required. As in COPD, the ability to identify patients with a better prognosis is likely to depend on assessing multiple factors such as the degree of hypoxia and hypercapnia, evidence of cor pulmonale, and limited functional capacity. Colonization with multidrug-resistant *P. aeruginosa*, *Staphylococcus aureus*, *Stenotrophomonas maltophilia*, or *Aspergillus fumigatus* is not a contraindication to transplantation, because these organisms have not been shown to affect posttransplantation survival. The exception is *B. cepacia* genomovar III, which is associated with unacceptably high posttransplantation mortality. Patients with multidrug-resistant pathogens should undergo frequent evaluation for changes in their colonizing microflora and resistance patterns. This will guide early prophylaxis and treatment in the immediate postoperative period. Complicated pneumothorax and hemoptysis are other indications for early referral.

Patients with CF have excellent survival rates, similar to those in persons with COPD. Although other causes of bronchiectasis also are amenable to transplantation, data on these disorders are insufficient to develop specific guidelines. For the most part, guidelines recommended for patients with CF are used.

Pulmonary Arterial Hypertension

Idiopathic pulmonary hypertension is a progressive and rapidly fatal disease, with an estimated median untreated survival of less than 3 years from the time of diagnosis. Current pulmonary vasodilator therapy (with agents including epoprostenol, treprostinil, sildenafil, and bosentan) has substantially increased survival. Transplantation is, accordingly, reserved for those who do not respond to medical management. Patients in New York Heart Association/World Health Organization (NYHA/WHO) functional class III or IV are at highest risk for death and the most likely to benefit from transplantation. Diminished exercise capacity can be measured by use of a standard 6-minute walk test. Inability to walk a distance of 332 m and degree of right-sided heart failure are important predictors of mortality.

DONOR SELECTION AND MANAGEMENT

The LAS assigns donor lungs to transplant candidates by use of a scoring system determined by medical urgency and net transplant benefit (predicted posttransplantation survival minus predicted wait list survival). Since its implementation in the United States in 2005, median waiting times have shortened markedly. Unfortunately, a scarcity of donated organs remains a limiting problem, leading to use of non–heart-beating donors (Table 75-4), ex vivo donor lung resuscitation, use of “bridges to transplant,” and development of different types of lung grafts (Table 75-5).

Currently, the Ideal Donor Selection Criteria are more stringent than those used for selecting other solid organs. In light of the scarcity of available lung grafts, many suggest that donor criteria be made more flexible to expand the existing donor pool. Alternate criteria include donor age older than 55 years, an initial PaO_2/FIO_2 ratio less than 300, the presence of pulmonary infiltrates on chest imaging, purulent secretions, and a positive history of use of tobacco or other inhalant drug (Table 75-6 and Box 75-1). Retrospective studies suggest similar outcomes for ideal and extended lung allograft recipients, specifically with respect to perioperative complications, ICU stay, requirements for mechanical ventilation, and 1-year survival rate (higher than 80% for both groups). Improved donor management also is under careful investigation, because it may help improve marginal donors and optimize them into ideal candidates. Optimizing donor status with reversal of any limiting physiologic insults is becoming the standard of care in most

Table 75-4 Maastricht Classification for Non-Heart-Beating Donors*

I	Uncontrolled	Brought in dead
II	Uncontrolled	Unsuccessful resuscitation
III	Controlled	Awaiting cardiac arrest
IV	Controlled	Cardiac arrest after brain death
V	Controlled	Cardiac arrest in a hospital inpatient

*Controlled non-heart-beating donors may be eligible for lung donation.

Table 75-5 Types of Lung Grafts

Living donor	Donor donates single lower lobe Recipient receives two lower lobes from two separate donors
Heart-beating donor	Whole brain death May donate one or both lungs, depending on selection criteria
Non-heart-beating donor (NHBD)	Donor has sustained cardiac arrest Resuscitated to unacceptable state and deemed suitable for organ donation
Xenotransplantation	Porcine, bovine, and primate lungs Still under investigation
Artificial lung	Intracorporeal or paracorporeal devices that oxygenate venous blood Still under investigation
Avalon Elite (Wang-Zwische double cannula)	Cannula inserted from the right jugular vein into superior vena cava (SVC) traversing right atrium to inferior vena cava (IVC) Drains venous blood from SVC and IVC and delivers oxygenated blood into the right atrium Achieves minimal to no recirculation and potential total gas exchange

From Wang D, Zhou X, Liu X, et al: Wang-Zwische double-lumen cannula—toward a percutaneous and ambulatory paracorporeal artificial lung, *ASAIO J* 54(6):606-611, 2008.

Table 75-6 Donor Selection Guidelines

Feature	Ideal Donor	Extended Donor
Age (years)	<55	>55
ABO	Identical or compatible	Compatible
Chest radiograph	Clear	Unilateral or focal infiltrate
*PaO_2 (mm Hg)	>300	<300 on initial assessment; must be >300 after optimization
Tobacco (smoking) history	<20 pack-years	>20 pack-years
Trauma	Absence of chest trauma	Trauma without significant abnormality
Sputum	No purulent secretions	May be considered, therapeutic suctioning Can be performed
Gram stain	Absence of organisms	Certain organisms may be considered (see Box 75-1)

*Partial pressure of arterial oxygen tension (PaO_2) is measured on a fraction of inspired oxygen of 1.0 and a positive end-expiratory pressure of 5 cm H_2O.

Box 75-1 Donor-Related Infections/Factors That May Be Compatible with Donor Eligibility

Gram-positive bacteremia
Mycobacterial infection outside chest
Fungal airway colonization
Hepatitis B core antibody
Herpesviruses (HHV6 to HHV8, varicella virus)
Cytomegalovirus (high risk if donor+/recipient−)
Epstein-Barr virus (high risk if donor+/recipient−)

HHV, human herpesvirus.

transplant centers (Figure 75-10). Common respiratory insults are caused by aspiration, atelectasis, infection, pulmonary edema, and the hemodynamic instability associated with neurologic dysfunction. Ventilatory strategies to improve alveolar ventilation may be implemented, along with therapeutic bronchoscopy to suction excess secretions and reexpand atelectatic lung. Small-volume bronchoalveolar lavage (BAL) can minimize the amount of alveolar flooding. Adequate tissue perfusion and cardiac function should be aided with vasoactive medications when needed. Repletion of cortisol, vasopressin, and thyroid hormone also may be of benefit (Figure 75-11).

DONOR GRAFT MANAGEMENT

Graft ischemic time begins after the lungs have been extracted from the donor. The lungs are flushed with a cold heparinized preservation solution—modified Euro-Collins, low potassium dextran solution (LPD), and University of Wisconsin solutions are the most commonly used—and hypothermic preservation is maintained during transport at 4° C. These solutions have helped reduce the severity of ischemic injury. Additives such as surfactant and platelet and thrombin inhibitors are still under investigation. Donor lungs are matched according to compatibility in size and ABO blood group. A growing trend is for use of prospective lymphocyte and human leukocyte antigen (HLA) cross-matching, especially in sensitized persons. Cytomegalovirus (CMV) and Epstein-Barr virus (EBV) cross-matching is not routine, because such testing often is impractical. Each matching procedure has its supporters for certain situations, however.

LUNG ALLOGRAFT IMPLANTATION

The implantation of a lung allograft (Figure 75-12) depends on the planned procedure, surgical experience, and the previous surgical history of the recipient. Before all transplant procedures, the recipient's pulmonary function should be maximized, and management should continue through surgery (e.g., continuing pulmonary vasodilators).

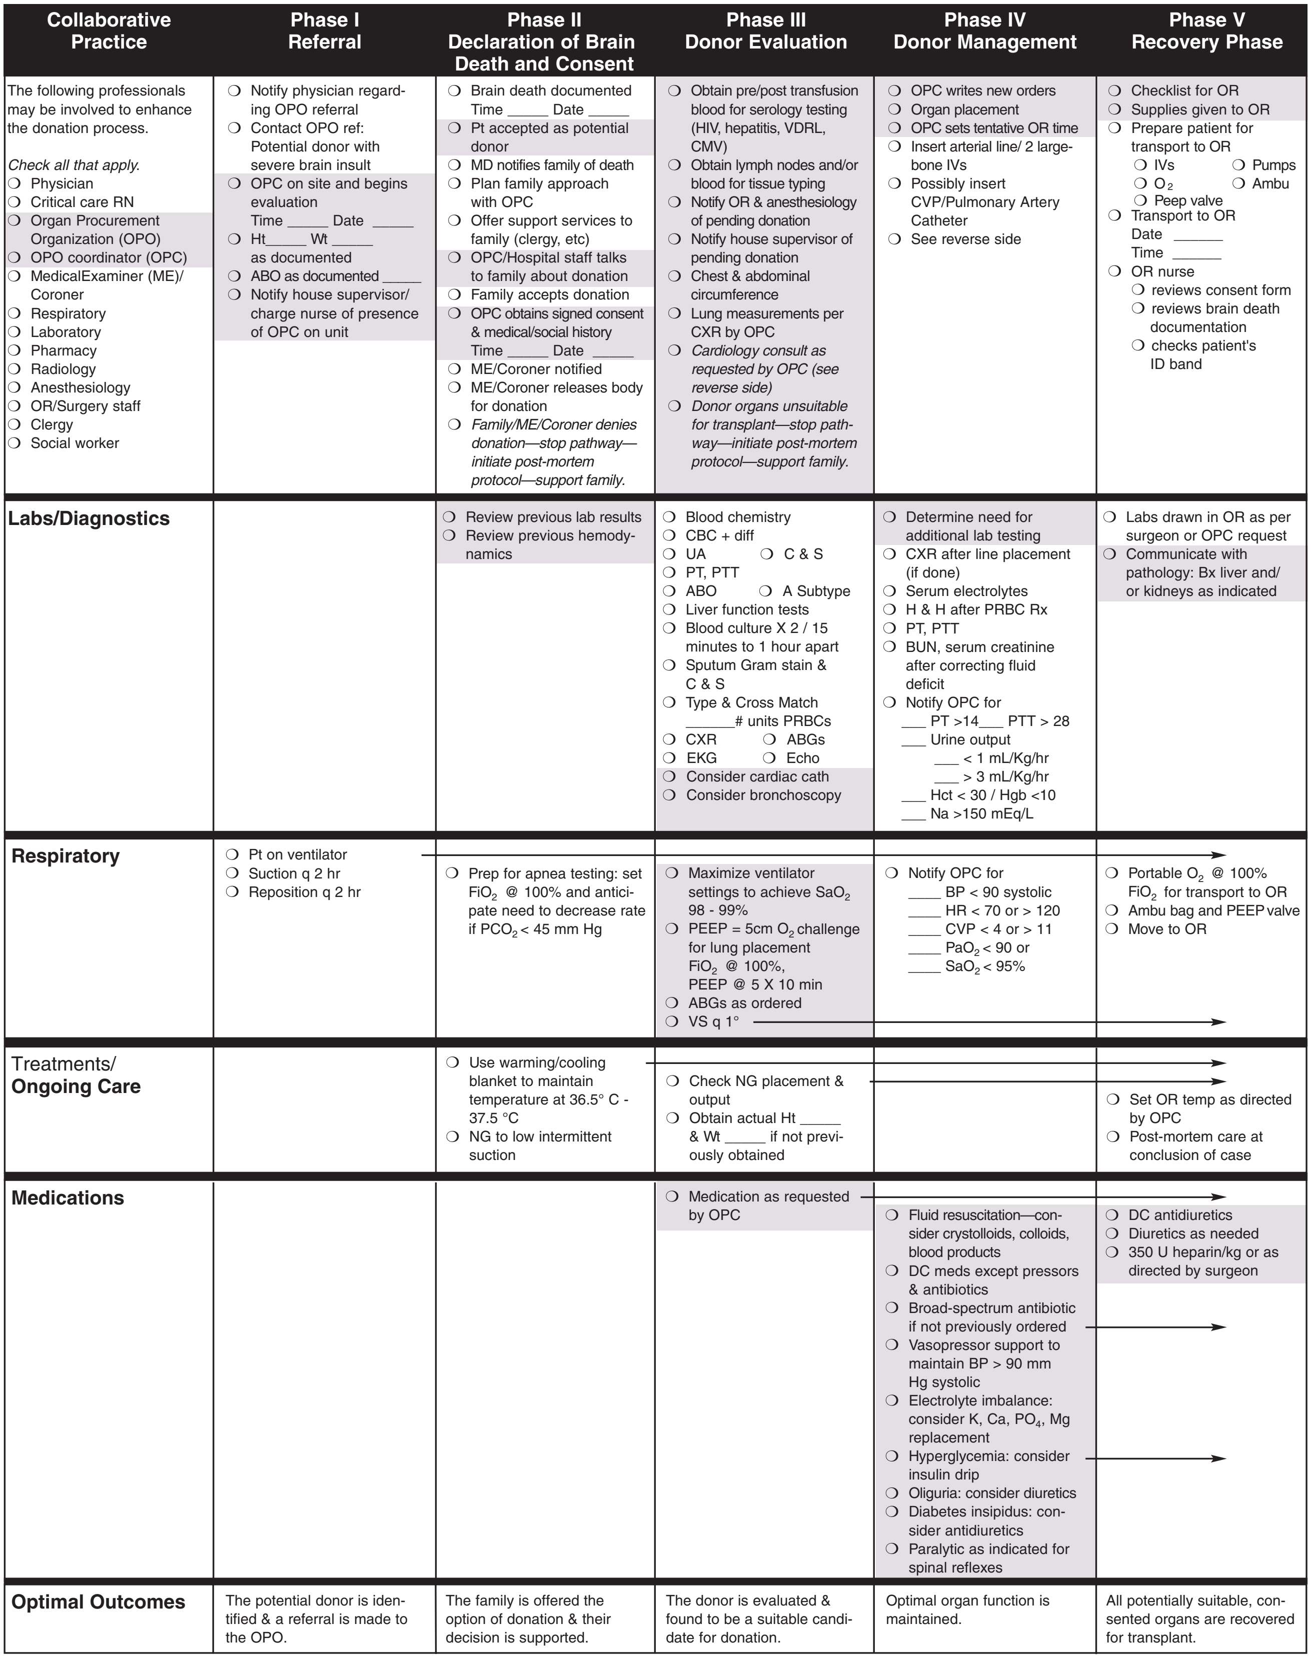
A single-lung transplant often is placed through an anterolateral or posterolateral thoracotomy. Bilateral lung implantation may be performed by means of a transverse sternotomy "clamshell" incision, at the level of the fourth or fifth intercostal spaces, whereas HLTx usually is done through a midsternotomy. Bilateral sequential lung transplantation (BSLT) also can be performed through bilateral anterior thoracotomies; this approach may be preferred because it does not split the sternum and is associated with less chest wall instability. The surgical history of the recipient is important, because previous pleurodesis or cardiothoracic surgery results in fibrous bands and adhesions. This makes resection difficult and may alter the anatomy. When a single-lung transplant procedure is to be performed, the intact side is preferred.

In most instances, the cold ischemic time for a single-lung transplant is approximately 4 hours and for a bilateral lung transplant is less than 6 hours. Pleural tubes are placed before closure and maintained in place until drainage is less than 200 mL/day. Bronchoscopic evaluation of the airway mucosa, anastomotic sites, and therapeutic suctioning of secretions is performed to document graft viability and optimize function.

Intraoperative and postoperative management of patients with end-stage pulmonary disease is challenging because of poor pulmonary gas exchange, elevated pulmonary vascular resistance, and right ventricular overload. Analgesia is controlled with multiple medications, with avoidance of narcotics if possible because of their effects of decreased respiratory drive and sedative properties. A thoracic epidural often is placed in preparation for surgery to adequately control pain and optimize postoperative lung function. Endotracheal intubation is performed with the largest-diameter dual-lumen tube possible to facilitate clearance of secretions. Mechanical ventilation can increase pulmonary vascular resistance and decrease venous return, leading to systemic hypotension. This potential for such effects is important to consider, because anesthetics used during rapid-sequence induction and surgery should be administered cautiously to avoid a precipitous drop in systemic vascular resistance. In most cases, infusions with propofol and fentanyl are used and combined with a neuromuscular blocker such as pancuronium. A fraction of inspired oxygen at 1.0 is used initially, to reduce hypoxic pulmonary vasoconstriction and limit right-sided heart afterload. Cardiopulmonary bypass is not used routinely and should generally be avoided unless hemodynamic instability arises or simultaneous cardiac surgery is necessary. If bypass is used, aprotinin (which slows fibrinolysis) may be administered to help control the coagulopathic disturbance created by the activation of multiple cytokines from the bypass procedure (although recent studies have suggested aprotinin may be associated with increased thrombotic complications). When single-lung ventilation commences, hypoxia and hypoventilation may ensue. Capnography, along with serial arterial blood gases, can help detect signs of failing single-lung ventilation. This deficit may be corrected with independent dual-lung ventilation and tolerance of moderate respiratory acidosis so long as hemodynamics and oxygenation remain stable.

Pulmonary vasodilators such as inhaled nitric oxide (iNO) are used commonly in the perioperative setting. The effects of iNO at relatively low levels (less than 20 parts per million) are not completely understood, but this agent is preferred because of the selective pulmonary vasodilation occurring at sites receiving adequate alveolar ventilation. iNO also seems to inhibit endothelial dysfunction and capillary leak, suppress oxygen radical formation, and ameliorate ischemia-reperfusion injury to the lung allograft. These benefits could then extend to improvement in early graft function. The adverse effects of iNO at higher concentration levels include methemoglobinemia, pulmonary edema, and cardiac contractile dysfunction. Prostacyclin, in either intravenous or aerosolized form, also is used as a direct pulmonary vasodilator.

The goal of hemodynamic management is to reach a negative fluid balance and limit pulmonary edema. The pulmonary artery occlusion pressure is kept under 10 mm Hg to ensure adequate preload. In most cases, immediate normalization of pulmonary arterial pressures and right ventricular function is expected after transplantation. To prevent alveolar damage, hyperinflation, pulmonary vascular hypertension, and



Collaborative Practice	Phase I Referral	Phase II Declaration of Brain Death and Consent	Phase III Donor Evaluation	Phase IV Donor Management	Phase V Recovery Phase
The following professionals may be involved to enhance the donation process. *Check all that apply.* ○ Physician ○ Critical care RN ○ Organ Procurement Organization (OPO) ○ OPO coordinator (OPC) ○ MedicalExaminer (ME)/ Coroner ○ Respiratory ○ Laboratory ○ Pharmacy ○ Radiology ○ Anesthesiology ○ OR/Surgery staff ○ Clergy ○ Social worker	○ Notify physician regarding OPO referral ○ Contact OPO ref: Potential donor with severe brain insult ○ OPC on site and begins evaluation Time _____ Date _____ ○ Ht_____ Wt _____ as documented ○ ABO as documented _____ ○ Notify house supervisor/ charge nurse of presence of OPC on unit	○ Brain death documented Time _____ Date _____ ○ Pt accepted as potential donor ○ MD notifies family of death ○ Plan family approach with OPC ○ Offer support services to family (clergy, etc) ○ OPC/Hospital staff talks to family about donation ○ Family accepts donation ○ OPC obtains signed consent & medical/social history Time _____ Date _____ ○ ME/Coroner notified ○ ME/Coroner releases body for donation ○ *Family/ME/Coroner denies donation—stop pathway—initiate post-mortem protocol—support family.*	○ Obtain pre/post transfusion blood for serology testing (HIV, hepatitis, VDRL, CMV) ○ Obtain lymph nodes and/or blood for tissue typing ○ Notify OR & anesthesiology of pending donation ○ Notify house supervisor of pending donation ○ Chest & abdominal circumference ○ Lung measurements per CXR by OPC ○ *Cardiology consult as requested by OPC (see reverse side)* ○ *Donor organs unsuitable for transplant—stop pathway—initiate post-mortem protocol—support family.*	○ OPC writes new orders ○ Organ placement ○ OPC sets tentative OR time ○ Insert arterial line/ 2 large-bone IVs ○ Possibly insert CVP/Pulmonary Artery Catheter ○ See reverse side	○ Checklist for OR ○ Supplies given to OR ○ Prepare patient for transport to OR ○ IVs ○ Pumps ○ O_2 ○ Ambu ○ Peep valve ○ Transport to OR Date ______ Time ______ ○ OR nurse ○ reviews consent form ○ reviews brain death documentation ○ checks patient's ID band

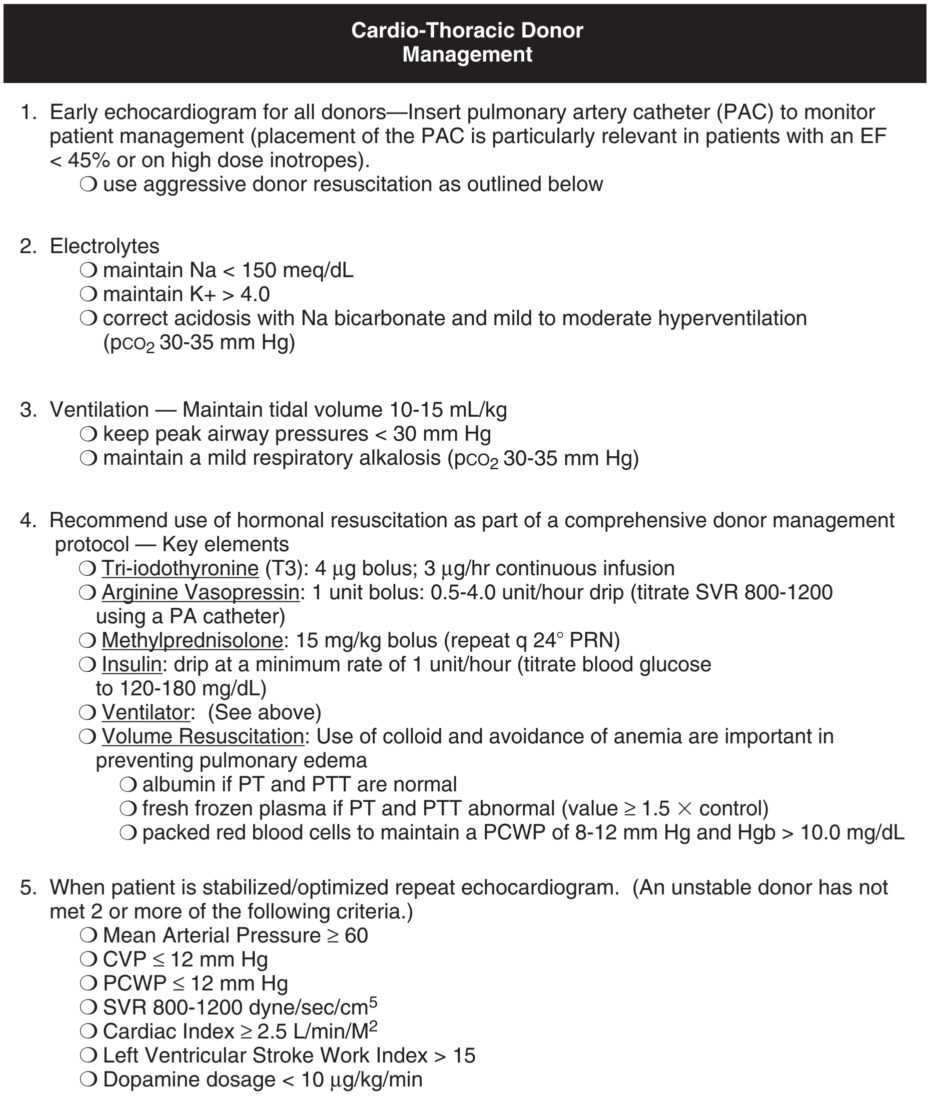
Figure 75-10 Critical pathway of organ donor management. *(From* Critical pathway for the organ donor, *Richmond, Va, United Network for Organ Sharing, 2006 [poster online]:* http://www.Unos.Org/Resources/Pdfs/Criticalpathwayposter.pdf.*)*



Cardio-Thoracic Donor Management

1. Early echocardiogram for all donors—Insert pulmonary artery catheter (PAC) to monitor patient management (placement of the PAC is particularly relevant in patients with an EF < 45% or on high dose inotropes).
   - ❍ use aggressive donor resuscitation as outlined below

2. Electrolytes
   - ❍ maintain Na < 150 meq/dL
   - ❍ maintain K+ > 4.0
   - ❍ correct acidosis with Na bicarbonate and mild to moderate hyperventilation (pco_2 30-35 mm Hg)

3. Ventilation — Maintain tidal volume 10-15 mL/kg
   - ❍ keep peak airway pressures < 30 mm Hg
   - ❍ maintain a mild respiratory alkalosis (pco_2 30-35 mm Hg)

4. Recommend use of hormonal resuscitation as part of a comprehensive donor management protocol — Key elements
   - ❍ Tri-iodothyronine (T3): 4 µg bolus; 3 µg/hr continuous infusion
   - ❍ Arginine Vasopressin: 1 unit bolus: 0.5-4.0 unit/hour drip (titrate SVR 800-1200 using a PA catheter)
   - ❍ Methylprednisolone: 15 mg/kg bolus (repeat q 24° PRN)
   - ❍ Insulin: drip at a minimum rate of 1 unit/hour (titrate blood glucose to 120-180 mg/dL)
   - ❍ Ventilator: (See above)
   - ❍ Volume Resuscitation: Use of colloid and avoidance of anemia are important in preventing pulmonary edema
     - ❍ albumin if PT and PTT are normal
     - ❍ fresh frozen plasma if PT and PTT abnormal (value ≥ 1.5 × control)
     - ❍ packed red blood cells to maintain a PCWP of 8-12 mm Hg and Hgb > 10.0 mg/dL

5. When patient is stabilized/optimized repeat echocardiogram. (An unstable donor has not met 2 or more of the following criteria.)
   - ❍ Mean Arterial Pressure ≥ 60
   - ❍ CVP ≤ 12 mm Hg
   - ❍ PCWP ≤ 12 mm Hg
   - ❍ SVR 800-1200 dyne/sec/cm^5
   - ❍ Cardiac Index ≥ 2.5 L/min/M^2
   - ❍ Left Ventricular Stroke Work Index > 15
   - ❍ Dopamine dosage < 10 µg/kg/min

Figure 75-11 Critical pathway of organ donor management. *CVP*, central venous pressure; *EF*, ejection fraction; *Hgb*, hemoglobin; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *PWCP*, pulmonary capillary wedge pressure; *SVR*, systemic vascular resistance. *(From* Critical pathway for the organ donor, *Richmond, Va, United Network for Organ Sharing, 2006 [poster online]: http://www.Unos.Org/Resources/Pdfs/Criticalpathwayposter.pdf.)*

anastomotic dehiscence, peak airway pressures are kept under 40 cm H_2O, with a positive end-expiratory pressure close to 5 cm H_2O. Liberation from mechanical ventilation usually is accomplished in the first 1 to 3 days after transplantation.

NONINFECTIOUS COMPLICATIONS

The most common problems in the immediate posttransplantation period are the same as those occurring in most postsurgical patients. Hypoxemia may stem from poor cardiac output, endotracheal tube displacement, or obstruction of uncleared secretions, leading to lobar atelectasis. Additional complications that are unique to lung transplantation include hyperacute rejection, graft dysfunction, and cardiac failure; each may be difficult to differentiate from the others (Table 75-7). A suggested reading by Ahya and Kawut has been listed.

HYPERACUTE REJECTION

Hyperacute rejection (HAR) results from a recipient antibody directed against donor endothelial antigens and those in the human leukocyte antigen (HLA) group. This antibody immediately triggers the classic complement cascade with reperfusion of the graft, leading to cell injury and cell death. HAR is extremely rapid in onset, occurring often within minutes of reperfusion and can be seen intraoperatively as a dusky pallor and swelling of the transplanted lung. Endothelial injury leads to capillary leak, and leukocyte injury leads to microvascular inflammation, thrombosis, and coagulopathy. The capillary injury is manifested as diffuse alveolar infiltrates, low PaO_2/FIO_2 ratio, and increased plateau pressures.

HAR can be avoided by preoperatively performing a leukocyte cross-match test, whereby the recipient's blood is tested against the donor's cells, seeking the presence of leukocyte sensitization and donor cell lysis. The plasma reactivity antibody (PRA) test is another way of checking the recipient's serum against a panel of commonly found HLAs and measuring the degree of sensitization. Patients with a PRA concentration greater than 10% are considered to be at greater risk for rejection and posttransplantation mortality. In our institution, patients with high PRA levels are treated with plasmapheresis followed by intravenous immunoglobulin (IVIG) on the day of transplantation. Prospective cross-matching and/or virtual cross-matching are routinely utilized. This combination treatment seems to provide outcomes comparable to those for recipients without high levels of anti-HLA antibodies. Other methods involve pulse administration of cyclophosphamide or methotrexate along with IVIG to reach a high level of immunosuppression. Desensitization routines vary, and it is as yet unclear how well they work.

Lung transplant techniques

	Heart-lung	Bilateral sequential	Single lung	Live donor lobar
				Incision	Midline sternotomy	Horizontal "clam shell" Bilateral anterior thoracotomies preferred Horizontal "clam shell" less frequently used	Lateral thoracotomy	Horizontal "clam shell"
Anastomoses	Tracheal Right atrial Aortic	Left and right bronchial "Double" left atrial Right and left pulmonary artery	Bronchial Left atrial Pulmonary artery	Lobar bronchus to bronchus Lobar vein to superior pulmonary vein Lobar artery to main pulmonary artery

Table 75-7 Early Noninfectious Pulmonary Complications

	Diagnosis			
Feature	**HAR**	**PGD**	**AR**	**HPE**
Onset	Immediate (<2 days)	2-3 days	1 week to 3 months	Immediate (<2 days)
Etiology	Recipient antibodies to donor antigens ABO blood group antigens HLA antigens (DR and B)	Multi-injury: Donor illness, surgical harvest, ischemia preservation hypothermia, reperfusion	Cell-mediated reaction against donor endothelial and epithelial antigens	Pulmonary venous obstruction Cardiogenic shock LV outflow obstruction Fluid overload
Pathology	Alveolar hemorrhage Intravascular fibrin/thrombi Neutrophil interstitial infiltration Capillaritis IgG deposition	DAD Graded by level of hypoxemia	Graded by extent of parenchymal and vascular lymphocytic infiltration T cell infiltration, $CD8^+$ predominant	Alveolar edema
Treatment	Removal of alloantibodies Plasmapheresis IVIG	Negative fluid balance Lung-protective ventilation Nitric oxide Prostaglandins ECMO Retransplantation	Cell-mediated immunosuppression High-dose steroids Antithymocyte globulin Photopheresis Radiation	Negative fluid balance Diuresis Renal replacement therapy Correction/treatment of underlying cause

AR, acute rejection; *DAD*, diffuse alveolar damage; *ECMO*, extracorporeal mechanical oxygenation; *HAR*, hyperacute rejection; *HLA*, human leukocyte antigen; *HPE*; high-pressure pulmonary edema; *IgG*, immunoglobulin G; *IVIG*, intravenous immunoglobulin; *LV*, left ventricle; *PGD*, primary graft dysfunction.

Table 75-8 Recommendations for Grading of Primary Graft Dysfunction Severity

Grade	PaO_2/FIO_2 Ratio	Radiographic Infiltrates Consistent with Pulmonary Edema
0	>300	Absent
1	>300	Present
2	200-300	Present
3	<200	Present

From Christie JD, Carby M, Bag R, et al: Report of the ISHLT Working Group on Primary Lung Graft Dysfunction. Part II: definition. A consensus statement of the International Society for Heart and Lung Transplantation, *J Heart Lung Transplant* 24(10):1454–1459, 2005.

PRIMARY GRAFT DYSFUNCTION

Primary graft dysfunction (PGD) is the current name for the syndrome of acute lung injury (ALI) after reperfusion of the lung allograft (Table 75-8). This entity previously was referred to as ischemia-reperfusion injury, reimplantation edema, or early graft dysfunction. PGD occurs 48 to 72 hours after transplantation and is characterized by development of bilateral diffuse alveolar infiltrates evident on plain chest radiograph coupled with hypoxemia resulting from capillary leak and alveolar flooding and is associated with prolonged ischemic time (i.e., longer than 550 minutes). In approximately 15% of patients, the degree of hypoxemia reaches ALI criteria (PaO_2/FIO_2 ratio less than 200) with an accompanying mortality rate of more than 60%. Exclusion of other causes of alveolar infiltrates, including high-pressure pulmonary edema, is necessary.

Immediate management is supportive and similar to management of patients with ALI or acute respiratory distress syndrome (ARDS), including generating a negative fluid balance in an attempt to prevent further alveolar flooding by use of open lung plus low tidal volume ventilation (4 to 6 mL/kg of predicted body weight) to limit ventilator-associated lung injury and providing hemodynamic support with vasoactive drugs to maintain adequate perfusion to major organs and the bronchial anastomoses. Renal replacement therapy generally is recommended for oliguric renal injury, because it may facilitate achieving negative fluid balance. Anecdotal evidence suggests that nitric oxide may lower pulmonary arterial pressures, improve ventilation-perfusion mismatch, and protect endothelial cells. Similarly, prostaglandins also may have protective effects in this setting and often are added to the preservation solution as a means of preventing PGD. Extracorporeal membrane oxygenation (ECMO) as a bridge to urgent retransplantation has been used anecdotally with little success.

HIGH-PRESSURE PULMONARY EDEMA

High-pressure pulmonary edema (i.e., a pulmonary artery occlusion pressure greater than 18 mm Hg) can develop as a result of several problems. Fluid overload may occur from blood product transfusion and/or crystalloid infusions. Cardiogenic shock can occur as result of cardiopulmonary bypass or from previously untreated myocardial disease. Pulmonary vascular anastomoses may undergo dehiscence or become thrombosed or stenosed. Diagnosis of pulmonary venous obstruction can be made with transesophageal echocardiography with careful inspection of the pulmonary valve anastomotic sites. Thrombus formation in the pulmonary outflow tract and left atrium can lead to systemic embolization, necessitating immediate anticoagulation with or without thrombectomy.

ACUTE REJECTION

Acute rejection (AR) is a cell-mediated event activated by donor antigens. It occurs in about 40% of transplant recipients in the first year alone with the highest incidence at 6 months after lung transplantation and is irrespective of specific induction treatment. Figure 75-13 shows the reported rejection between discharge and 1-year follow-up stratified by immunosuppressive regimen. It manifests with presence of alveolar infiltrates on the chest radiograph, hypoxemia, and fever, but many patients may be asymptomatic. Histologic examination (Figure 75-14) is required to diagnose AR, because the clinical presentation mimics that in pulmonary infection, and increasing immunosuppression empirically can lead to toxicity, infection, and malignancy.

AR is associated with an increased risk for development of chronic rejection. For this reason, serial surveillance with fiberoptic bronchoscopy, BAL, and transbronchial biopsy is often routine during the first year after transplantation. Current recommendations are to obtain at least five separate samples that contain both alveolated lung and bronchioles (because both are necessary to grade the level of AR). Treatment centers on increasing the level of immunosuppression by administration of high-dose corticosteroids and optimizing the use of the standard agents. In addition, antithymocyte globulin, photochemotherapy, and lymphoid irradiation may be used.

BRONCHIAL ANASTOMOTIC COMPLICATIONS

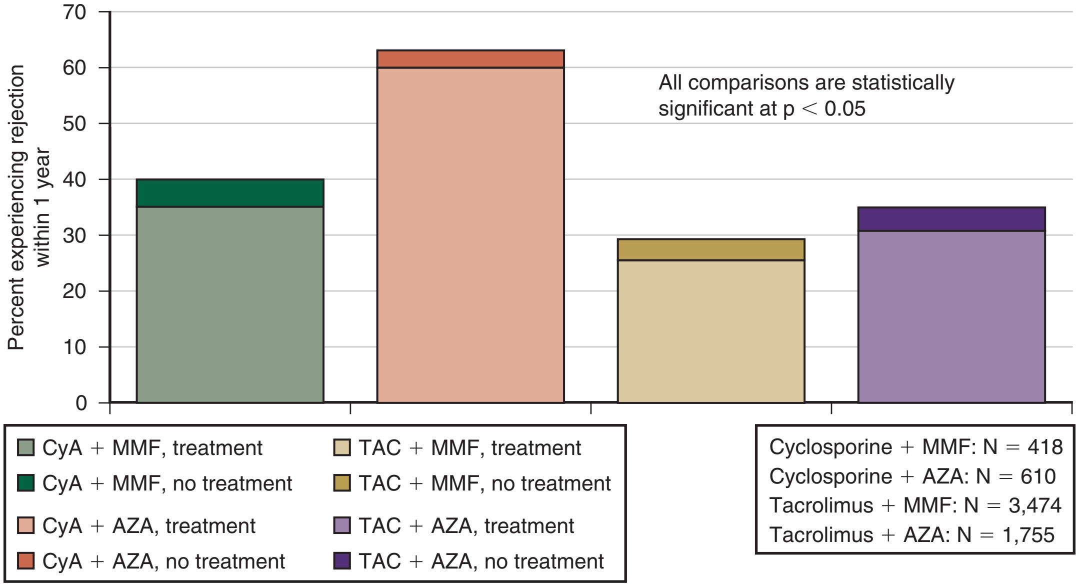
Bronchial anastomotic dehiscence may result from ischemic injury, infection, or poor healing. Bronchial artery interruption during the transplant procedure disrupts perfusion to the large airways. High doses of corticosteroids impair wound healing, potentially leading to bronchomalacia and stenosis (Figure 75-15). Dehiscence may manifest as pneumomediastinum, pneumopericardium, and/or pneumothorax (Figure 75-16). Fiberoptic bronchoscopy is necessary to ensure that all bronchial anastomoses are intact. Correction consists of treating any underlying infection and maintenance of adequate tissue perfusion. Bronchial stent placement, laser ablation, and balloon dilatation often are used in management; rarely is reoperation considered.

PHRENIC NERVE INJURY

Phrenic nerve injury occurs from trauma during intraoperative manipulation of the mediastinum and pericardium. Phrenic nerve dysfunction can occur as a result of hypothermic cardioplegia and stretch injury. Both may complicate weaning. This diagnosis should be suspected in patients who exhibit a paradoxical breathing pattern. An elevated hemidiaphragm may not be obvious on radiography or on fluoroscopic or ultrasound evaluation of diaphragmatic motion if the injury is bilateral. In such instances, a phrenic nerve conduction study would be the definitive diagnostic study of choice.

HYPERINFLATION

Hyperinflation of the native lung may be seen in patients with COPD and unilateral lung transplantation as a result of the higher lung compliance, more severe airway obstruction, and air trapping that occurs in the remaining emphysematous lung.



Treated rejection = Recipient was reported to (1) have at least one acute rejection episode that was treated with an anti-rejection agent; or (2) have been hospitalized for rejection.
No rejection = Recipient had (i) no acute rejection episodes and (ii) was reported either as not hospitalized for rejection or did not recieve anti-rejection agents.

Figure 75-13 Reported rejection between discharge and 1-year follow-up for adult lung transplant follow-ups from July 2004 through June 2010, stratified by maintenance immunosuppressive regimen. Rejection is classified as treated *(lighter color)* or untreated *(darker color). AZA,* azathioprine; *CyA,* cyclosporine A; *MMF,* mycophenolate mofetil; *TAC,* tacrolimus. Analysis is limited to patients who were alive at the time of the follow-up. *(Adapted from Christie JD, Edwards LB, Kucheryavaya AY: The Registry of the International Society for Heart and Lung Transplantation: Twenty-eighth adult lung and heart-lung transplant report—2011,* J Heart Lung Transplant *30:1104-1122, 2011.)*

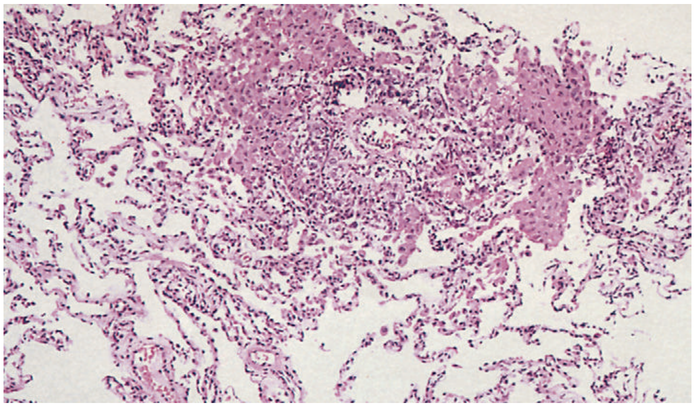


Figure 75-14 Transbronchial lung biopsy specimen showing acute rejection. The lymphocytes surround an arteriole and the infiltrate spreads into surrounding alveolar walls (grade A3).

The hyperinflated lung can compress the transplanted lung and/or the mediastinal structures, causing a substantial reduction in function (Figure 75-17).

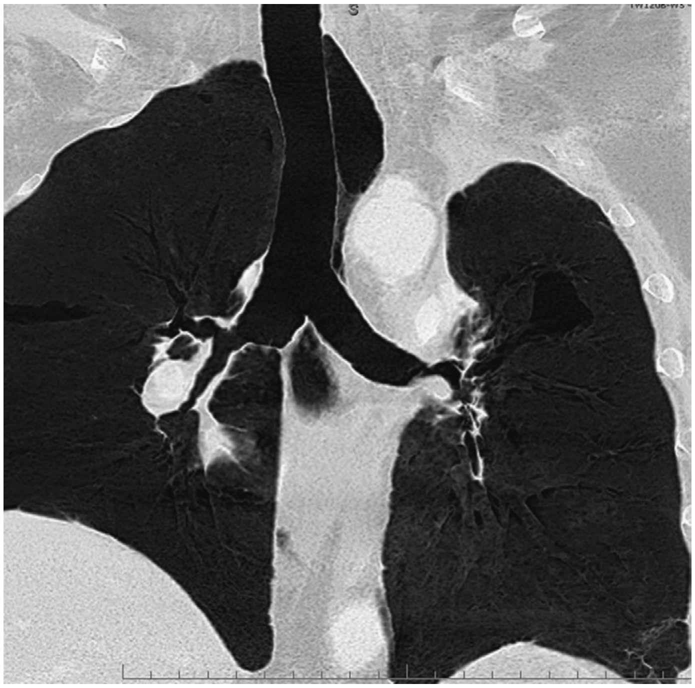

Figure 75-15 CT scan of bilateral bronchial stenosis (distal main bronchi) after bilateral sequential lung transplantation. Poor anastomotic perfusion from septic shock and bacterial pneumonia complicated the immediate postoperative course.

INFECTIOUS COMPLICATIONS

Infectious complications in the immediate postoperative period are the same as those associated with other major cardiothoracic surgery. Blood-borne infections from indwelling catheters, urinary tract, and wound complications are common. Pneumonia in the acute posttransplantation phase requires careful assessment of the donor's and recipient's microbiologic and clinical histories, including previous bacterial colonization or recent infections. Clinical history is relevant, because it may detect risks for aspiration, nosocomial, and ventilator-associated pathogens (Table 75-9). Physiologic abnormalities in the transplanted lung also predispose to infection. Impaired mucociliary clearance, denervation of the cough reflex, and disruption of the pulmonary lymphatic and vascular outflow all may act in combination. Infection of the allograft results in inflammation and graft damage. Although prophylaxis seems logical in

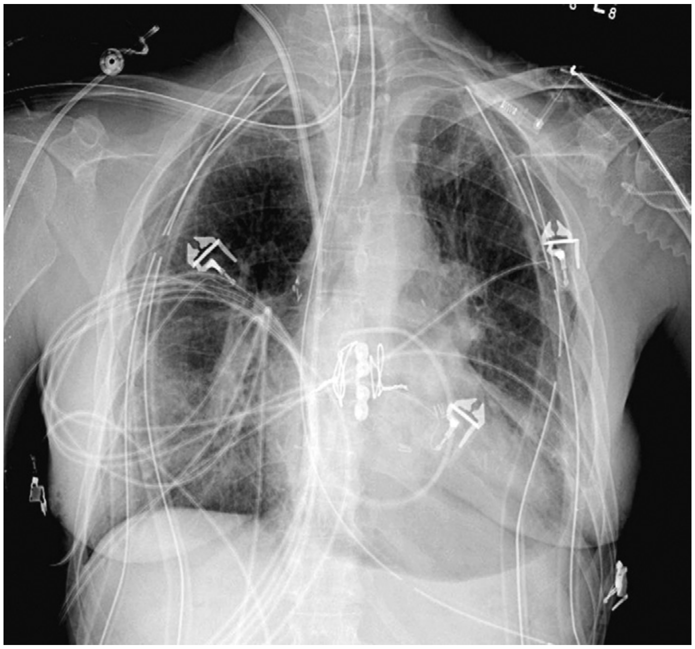

Figure 75-16 Chest radiograph showing pneumopericardium arising as a manifestation of bronchial dehiscence after lung transplantation.

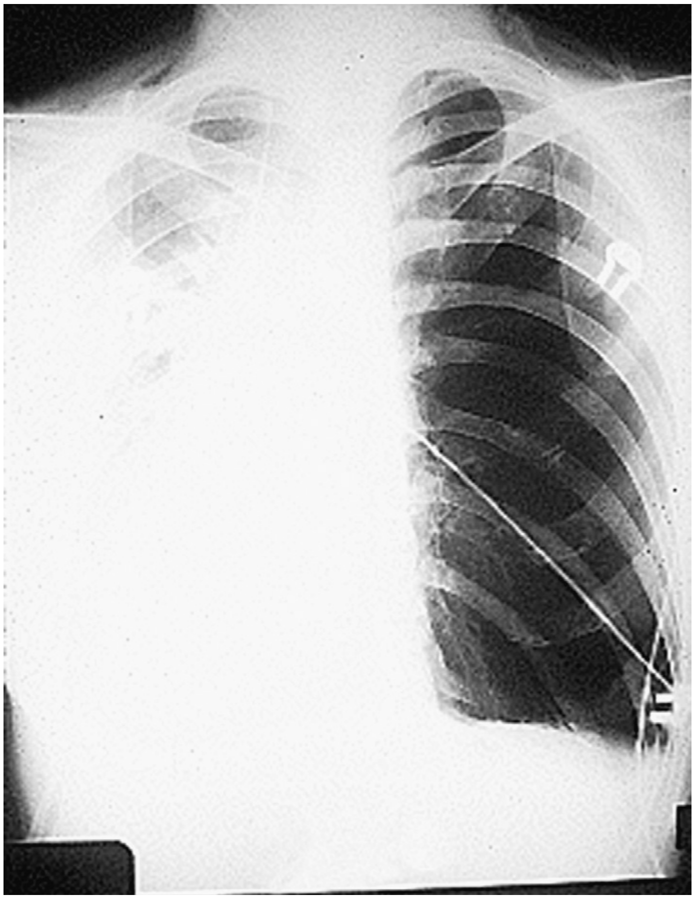

Figure 75-17 Chest radiograph showing right single-lung transplant for emphysema. Severe hyperinflation with mediastinal shift caused by overinflation of the native lung with compression of the transplanted right lung is evident.

preventing future infection, strong clinical evidence to support universal use of prophylaxis is lacking, with variable findings among different transplant centers worldwide.

COMMUNITY-ACQUIRED PNEUMONIA

Pneumonia manifesting in the first month after transplantation usually is bacterial in origin. Community- or hospital-acquired gram-positive and gram-negative bacteria are the most common pathogens. Aspiration is another cause, because donors are at risk of aspiration from emergency intubation, neurologic impairment, and/or critical illness. In donors who have been intubated for more than 48 hours, pneumonia should be considered to be ventilator-associated. Patients with a history of bacterial pneumonia must be treated and guided by the sensitivity and resistance patterns previously documented. With identification of the pathogens responsible for bacterial infection in the donor, appropriate antibiotic coverage should be provided.

Early fiberoptic bronchoscopy with BAL and transbronchial biopsy (TBB) constitutes the standard of care in the early posttransplantation period. Specimens are routinely sent for bacterial, fungal, and viral analysis. Methicillin-resistant *Staphylococcus aureus* (MRSA) and resistant *Pseudomonas aeruginosa* should be suspected in patients at risk for nosocomial infection or colonization, such as in those with CF. Prophylaxis with nebulized antipseudomonal drugs such as tobramycin and colistin may be useful.

OPPORTUNISTIC INFECTIONS

Opportunistic infections are uncommon before the first month after transplantation. They are directly related to the immunosuppressed state that leads to the reactivation of latent infections and an inadequate response to otherwise nonvirulent pathogens. Prophylaxis against *Pneumocystis*, the Herpesviridae family of viruses, and *Aspergillus* will reduce the frequencies of these infections; however, opportunistic infection is a common contributor to posttransplantation morbidity.

Cytomegalovirus (Human Herpesvirus Type 5)

CMV is found in latent stage in nearly 60% of all adults. Routine screening of donor and recipient for CMV IgG allows stratification of patients at highest risk for CMV reactivation and pneumonitis. Primary CMV infection occurs when a CMV-seronegative recipient becomes infected from a CMV-positive graft or blood product. Because primary CMV infection is associated with the highest risk for severe morbidity and mortality, matching CMV-negative recipients to CMV-negative donors is preferred but sometimes is impractical. In cases in which CMV-naive recipients receive a CMV-positive graft, passive immunization with intravenous CMV IgG can be given, followed by inhibition of viral replication with ganciclovir. Other anti-CMV agents include valganciclovir, cidofovir, foscarnet, and leflunomide. These may be used in refractory or resistant cases. Secondary CMV infection and CMV superinfection can cause reactivation pneumonitis in CMV-seropositive recipients; however, these types of infections are not as severe as primary CMV infection. An oral prodrug for cidofovir may be available soon for therapy or prevention.

CMV pneumonitis can be diagnosed by the presence of intranuclear viral inclusion bodies on histologic examination. This condition may be an indirect cause of rejection and the bronchiolitis obliterans syndrome (Figure 75-18). CMV

Table 75-9 Infectious Pulmonary Complications

Primary CMV infection
Antilymphocyte antibodies
Infection, fever
Graft rejection
Active CMV infection: Local replication or migration of infected cells to local site of infection
Latent CMV infection
↑ Proinflammatory cytokines (esp. TNF-α), ↑ NFkB
Activation of anti-CMV immunity: CD4+ memory T cells CD8+ cytotoxic T cells Antibodies
Flu-like and mononucelosis-like syndromes
Activation of innate inflammatory response ↑ adhesion molecules (ICAM1, VCAM, vWF) Leukocyte adhesion, complement activation, coagulation
Organ-specific disease (i.e., pneumonia)
Systemic and local immunosuppression (opportunistic infections)
Cellular effects
Activation of other viruses (e.g., EBV)
↑ Cell surface antigens (e.g., MHC) Acute/chronic graft rejection

Figure 75-18 The direct and indirect effects of cytomegalovirus infection. The activation of latent cytomegalovirus (CMV) alters many aspects of the innate and adaptive immune response. The indirect effects include predisposition to opportunistic infections, activation of other latent viruses, and graft rejection or graft-versus-host disease. *EBV*, Epstein-Barr virus; *ICAM1*, intercellular adhesion molecule-1; *MHC*, major histocompatibility complex; *TNF-α*, tumor necrosis factor-α; *VCAM*, vascular cell adhesion molecule; *vWF*, von Willebrand factor. *(From Ison MG, Fishman JA: Cytomegalovirus pneumonia in transplant recipients,* Clin Chest Med *26:691–705,viii [Figure 1], 2005.)*

prophylaxis often is given routinely and may delay acute infection (**Table 75-10**). This practice, however, may result in the evolution of resistant strains and predispose the patient to antiviral toxicity, as well as increasing the current cost of care. Alternatively, preemptive monitoring and treatment of infection can be implemented. CMV replication can be detected early by rising serum CMV antigen levels or quantitative CMV polymerase chain reaction (PCR) assay results.

Epstein-Barr Virus

EBV is also routinely screened for in both recipients and donors. Similar to CMV, it carries a high risk for reactivation and can lead to posttransplantation lymphoproliferative disorder (PTLD). PTLD is believed to occur in almost half of the patients who are EBV-seronegative and receive an EBV-seropositive graft. Matching EBV-negative status is therefore extremely important, but often difficult, because few donor agencies screen

Table 75-10 Suggested CMV Prophylaxis After Lung Transplantation

CMV Status	Recipient +	Recipient –
Donor +	• Treatment duration is 3 months 1. Days 1-14: Valganciclovir 900 mg PO bid 2. Days 15-90: Valganciclovir 900 PO mg daily	• *Donor +/Recipient – are the highest risk for CMV disease* • Prophylaxis may have advantage over preemptive therapy • Treatment duration is typically 6 months 1. Days 1-14: Valganciclovir 900 mg PO bid 2. Days 15-180: Valganciclovir 900 mg PO daily*
Donor –	• Treatment duration is 3 months 1. Days 1-14: Valganciclovir 900 mg PO bid 2. Days 15-90: Valganciclovir 900 PO mg daily	• Risk of CMV disease is increased with extensive blood transfusion • Leukodepleted and CMV seronegative blood products are recommended • If extensive transfusions are necessary, CMV prophylaxis should be considered • Monitoring weekly for CMV PCR should be considered • We use Acyclovir or Valacyclovir for HSV prophylaxis days 1-90
Additional Considerations: • Dosing must be adjusted for renal function • CMV PCR assay is followed routinely if prophylaxis is not given • Cytogam (CMV immunoglobulin) 150 mg/kg can be added for treatment • Monitor clinically for signs and symptoms of late onset CMV disease		

*When used as prophylaxis, the dose of Valganciclovir is 900 mg daily, versus treatment dose which is 900 mg twice daily.
CMV, cytomegalovirus; *HSV*, herpes simplex virus; *PCR*, polymerase chain reaction.

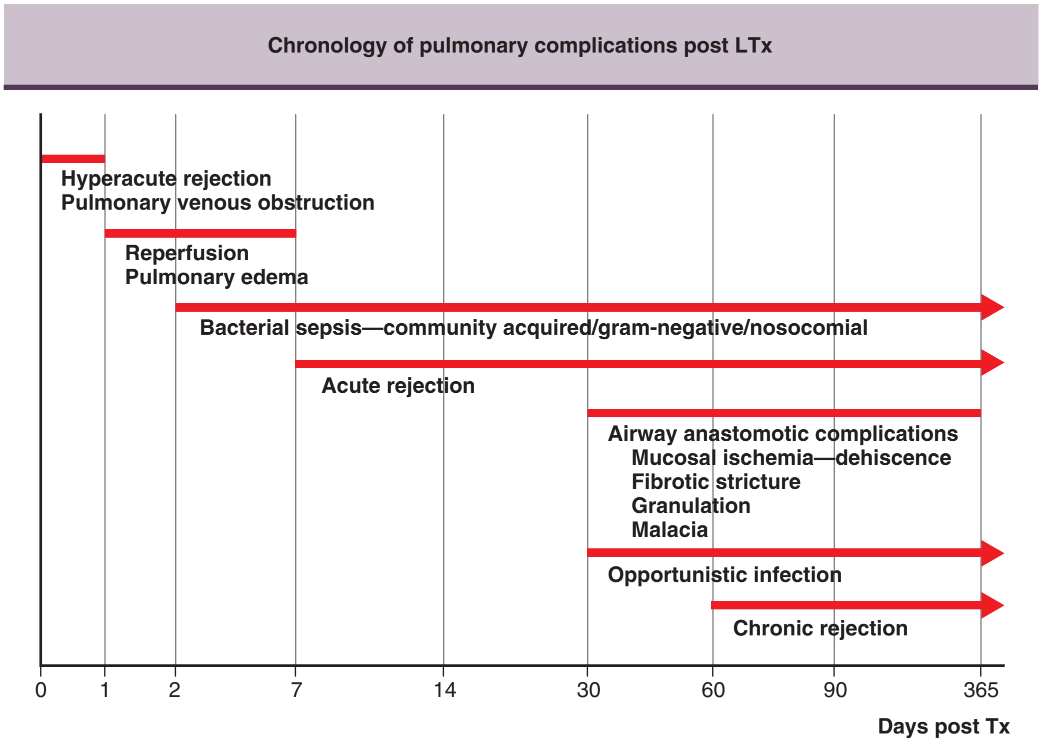

Figure 75-19 The chronology of pulmonary complications in the lung transplant recipient. Some complications occur during a defined time span in the early posttransplantation period, but others occur throughout the follow-up period.

for EBV. PTLD may manifest as a pulmonary nodule, mass, or infiltrate and requires tissue biopsy for diagnosis. Unfortunately, commonly used chemotherapy directed against lymphoproliferative malignancies has not been very successful in treating PTLD. EBV prophylaxis in patients at highest risk is covered by antiviral treatment directed against CMV and herpes simplex virus (HSV). As with all other opportunistic complications, reduction in the level of immunosuppression remains the single most important management strategy, if PTLD occurs.

Aspergillus Spp.

Aspergillus infection is a common infection after solid organ transplantation. It may manifest in a variety of ways, including a bronchial inflammatory disorder, necrotizing airway infection (with pseudomembrane formation), and invasive pulmonary parenchymal aspergillosis. Invasive fungal infection is difficult to diagnose, because it is angiocentric and not detected on routine BAL or TBB. Surgical biopsy often is necessary to make a definite diagnosis. Prophylaxis with oral amphotericin B, itraconazole, voriconazole, or intravenous liposomal amphotericin may be administered to persons at highest risk for infection. The azoles must be used carefully, because they can interfere with the metabolism of calcineurin inhibitors.

A chronology for the common infectious and noninfectious complications that occur after transplantation over time is presented in Figure 75-19.

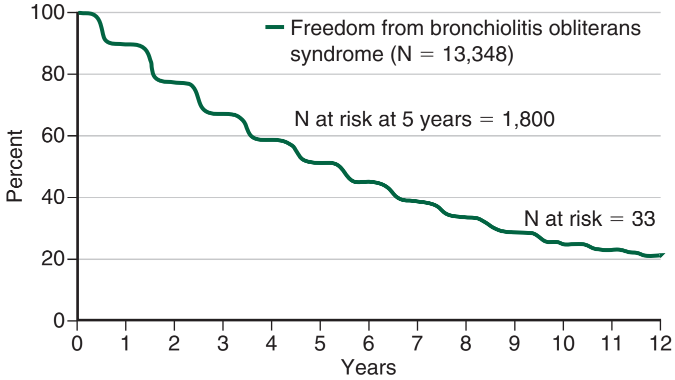

Figure 75-20 Freedom from bronchiolitis obliterans syndrome in adult lung recipients for follow-up assessments between April 1994 and June 2010, conditional on survival to 14 days. *(Adapted from Christie JD, Edwards LB, Kucheryavaya AY: The Registry of the International Society for Heart and Lung Transplantation: Twenty-eighth adult lung and heart-lung transplant report—2011,* J Heart Lung Transplant *30:1104-1122, 2011.)*

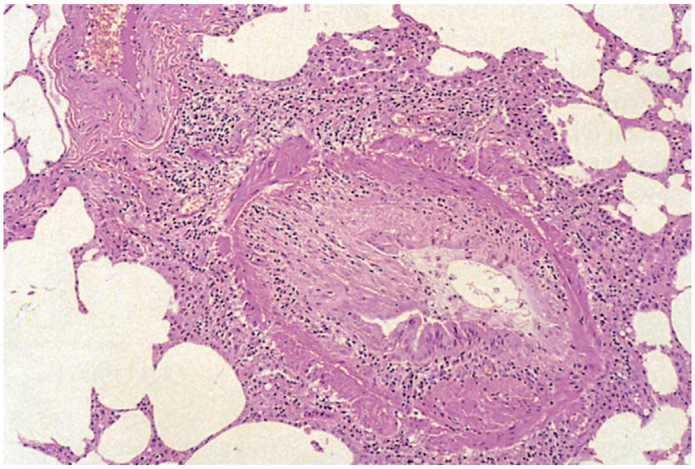

Figure 75-21 Open lung biopsy specimen showing obliterative bronchiolitis. The bronchiolar lumen is obliterated by organizing fibrin, myofibroblasts, and lymphocytes.

Table 75-11 Histologic Classification and Grading of Pulmonary Allograft Rejection

Acute Rejection	
Grade 0—none	No significant abnormality
Grade 1—minimal	Infrequent perivascular mononuclear cell infiltrates mainly surrounding venules that are 2-3 cells deep
Grade 2—mild	More frequent infiltrates, 5 cells or more deep, involving venules and arterioles
Grade 3—moderate	More exuberant mononuclear cell infiltrate that extends from the perivascular space into the alveolar Interstitium
Grade 4—severe	Infiltrate extending into the alveolar space with pneumocyte damage and at times necrosis of vessels and lung parenchyma
Airway inflammation	Lymphocytic bronchitis/bronchiolitis; pathologist may grade
Chronic Rejection	
Chronic airway rejection Active Inactive	
Chronic vascular rejection-accelerated graft vascular sclerosis	

CHRONIC REJECTION

Chronic Lung Allograft Dysfunction

Bronchiolitis obliterans syndrome (BOS) is a common clinicopathologic syndrome of progressive and irreversible airway obstruction with a declining DLCO that occurs as a late complication in graft function with an incidence of almost 50% by the fifth year after transplantation (Figure 75-20). On histopathologic examination, BOS is represented by obliterative bronchiolitis (OB)—specifically, fibrosis of the small airways with intimal thickening and sclerosis of its accompanying vessel that lead to near-complete occlusion of the bronchiolar lumen and small airway obstruction (Figure 75-21). Chest imaging should yield normal findings in the early stages of BOS, which remains a diagnosis of exclusion at that time. Acute rejection, infection, drug-induced pneumotoxicity, and bronchial anastomotic obstruction must be excluded. Advanced BOS may appear as peripheral bronchiectasis with a loss of vascularity and atelectasis. A staging system has been created to aid in the diagnosis of BOS by the International Society of Heart and Lung Transplantation (Tables 75-11 and 75-12). Of importance, not all graft dysfunction is due to OB. A restrictive pattern is present in a significant minority of patients. Imaging may suggest peripheral encroachment of the lung volume and restrictive pulmonary function tests (PFTs). Therefore, the phraseology "chronic lung allograft dysfunction" (CLAD) is coming into use to account for more than one manifestation of chronic graft failure.

CLAD is believed to be caused by alloimmune tissue injury. Risk factors include a previous history of rejection episodes, viral infections, and the presence of lymphocytic bronchiolitis. Unfortunately, some patients with severe clinical BOS may not show histologic evidence of obliterative bronchiolitis on biopsy, whereas others with significant histologic evidence of BO may be asymptomatic. There is no effective treatment for BOS. Slowing of further progression may be possible with a trial of increased immunosuppression. This may be warranted in patients with an inflammatory-predominant stage of BOS. Retransplantation remains a potential option in a few selected cases. Treatments today do not differ between obstructive and restrictive CLAD.

IMMUNOSUPPRESSION

The goal of immunosuppression in all patients undergoing solid organ transplantation arises from a two-phase host-versus-donor rejection model. In the initial acute posttransplantation period, donor antigen-presenting cells (APCs) activate T cells to react against graft antigens. B cells also are activated by graft antigens and form antibodies directed against them. This first phase, often attenuated, is associated with a high level of immunosuppression and is termed *induction*. Induction is directed against blocking the APC to T cell interaction, preventing T cell proliferation, and B cell alloimmunization. The second phase of immunosuppression is termed *maintenance*. During the maintenance phase, the host apparently adapts to the graft. Doses of immunosuppressants can be lowered to avoid toxicity

Table 75-12 Comparison of Acute Rejection and Bronchiolitis Obliterans Syndrome

Feature	Acute Rejection	Bronchiolitis Obliterans Syndrome
Peak frequency	First 6 months	>3 months
Onset	Abrupt to subacute	Usually subtle
Symptoms/signs	Tightness in chest (immediate postoperative period) Cough (usually not productive) Dyspnea	Dyspnea with heavy exertion Cough (often productive)
Physiologic	Restrictive impairment Desaturation of arterial blood	Obstructive impairment Normoxia until late
Radiologic	Diffuse interstitial infiltrates Pleural effusions	No abnormality until disorder is far advanced Computed tomography evidence of bronchiectasis and mosaic pattern
Hematologic	Leukocytosis	Normal white blood cell count
Histologic	Perivascular mononuclear cell infiltrates Airway inflammation is variable	Obliterative bronchiolitis Atherosclerosis of pulmonary and bronchial arteries Pleural scarring
Response to treatment function	Majority of cases improve rapidly with intravenous corticosteroid	Forced expiratory volume in 1 second at best stabilized Majority of recipients show progressive decline in allograft

and infectious complications while stabilizing the adaptive immune response.

Induction is accomplished with antibodies directed against human lymphoid cells. Antithymocyte globulin and monoclonal antibodies directed against specific CD receptors found on human lymphocytes are used, including muromonab-CD3, alemtuzumab, basiliximab, and daclizumab. Of these, basiliximab and daclizumab have gained favor, because they target activated T cells and have fewer, less severe side effects. Depleting antibodies are used in combination with high-dose methylprednisolone, a calcineurin inhibitor, and an antiproliferative drug such as an antimetabolite or an mTor (mammalian target of rapamycin) inhibitor.

Maintenance therapy is based on a triple-drug regimen that includes a calcineurin inhibitor, an antimetabolite, and a corticosteroid. This triple therapy has been chosen on the basis of studies performed on other solid organ transplants showing improved survival and lower graft rejection episodes over alternate regimens.

CALCINEURIN INHIBITORS

Calcineurin inhibitors block the signal of activation between APCs and T cells. The classic agent in this group is cyclosporine, because it was the first effective immunosuppressant used in transplantation medicine. Tacrolimus is the second most commonly used calcineurin inhibitor and is now preferred in most lung transplant programs. Side effects of these drugs include nephrotoxicity, neurotoxicity, hemolytic uremic syndrome, posttransplantation diabetes mellitus, and hypertension.

ANTIMETABOLITES

The antimetabolites inhibit the proliferation of lymphocytes. They include inhibitors of purine synthesis such as mycophenolate mofetil (MMF) and azathioprine. MMF generally is preferred over azathioprine because of its better side effect profile. Recent studies suggest, however, that the two agents have a similar effectiveness. Accordingly, azathioprine is still preferred at some centers because of its relatively low cost.

MAMMALIAN TARGET OF RAPAMYCIN INHIBITORS

The mTOR inhibitors act by inhibiting the cell cycle and preventing T cell proliferation. Rapamycin, also known as sirolimus, is the classic mTOR inhibitor. Newer mTOR inhibitors include everolimus and temsirolimus. mTOR inhibitors used in conjunction with calcineurin inhibitors increase the incidence of nephrotoxicity and hemolytic uremic syndrome events. The mTOR inhibitors have antineoplastic properties and are used in treatment of several different types of cancers. Accordingly, these agents may have a potential role in treating PTLD. Extreme caution is warranted if mTOR inhibitors are used early after transplantation, because bronchial dehiscence can be a serious complication.

PITFALLS OF IMMUNOSUPPRESSIVE THERAPY

Common complications from the chronic use of immunosuppressive drugs vary, depending on the specific agent and the recipient's predisposing characteristics (Table 75-13). Toxicities may be severe and irreversible, as is evident in cases of posttransplantation malignancy. Frequent checks for metabolic derangements and end-organ toxicity are critical. Unfortunately, serum drug levels do not correlate with the dosage of administered drugs and are not predictive of the potential toxic effects, because these factors vary from person to person.

Reaching and maintaining an adequate level of immunosuppression are difficult, leading some researchers to consider case-by-case analysis for specific genetic polymorphisms that affect drug metabolism to tailor specific treatments to the individual patient. Adjunctive testing of immune activity by the measurement of adenosine triphosphate (ATP) levels may be a more accurate way to adjust dosing. These basic issues warrant further investigation, because they are likely to affect the future of immunosuppressive management.

A current trend is for the use of tacrolimus, MMF, and sirolimus (Figure 75-22). A recent study comparing azathioprine and MMF in lung transplant recipients failed to show a significant difference in prevention of BOS. Although there are multiple reasons why a difference was not observed, there is still

Table 75-13 Maintenance Immunosuppressive Drugs

Agent	Dose	Adverse Effects	Interactions
Cyclosporine (calcineurin inhibitor)	Whole-blood level 250-350 ng/mL	Nephrotoxicity, HUS, neurotoxicity, posttransplantation DM, hirsutism, gingival hyperplasia, gastroparesis, HTN, electrolyte disturbances	Increased by macrolides, azoles, calcium channel blockers, gastric motility agents Decreased by anticonvulsants, rifampin
Tacrolimus (calcineurin inhibitor)	Whole-blood trough level 10-20 ng/mL	Nephrotoxicity, HUS, neurotoxicity, posttransplantation DM, hyperlipidemia, HTN, electrolyte disturbances	Fatty meals decrease absorption Increased by macrolides, azoles, calcium channel blockers, gastric motility agents Decreased by anticonvulsants, rifampin
Azathioprine (antimetabolite)	2-2.5 mg/kg/day Adjust for WBC 4000-6000/mm^3	Leukopenia, anemia, thrombocytopenia, pancreatitis	Allopurinol in combination resulted in higher bone marrow toxicity
Mycophenolate mofetil (antimetabolite)	1000-1500 mg bid	GI symptoms can be improved if given q6h or lower total dose	Antacids, iron, and magnesium decrease absorption Increases levels of acyclovir and ganciclovir
Sirolimus (mTOR inhibitor)	Load 6 mg, then 2 mg/day (goal 10-20 ng/mL level)	Anemia, thrombocytopenia, leucopenia, HTN, electrolyte abnormalities, GI symptoms	Increased by macrolides, azoles, calcium channel blockers, gastric motility agents

DM, diabetes mellitus; *GI*, gastrointestinal; *HTN*, hypertension; *HUS*, hemolytic uremic syndrome; *WBC*, white blood cell count.

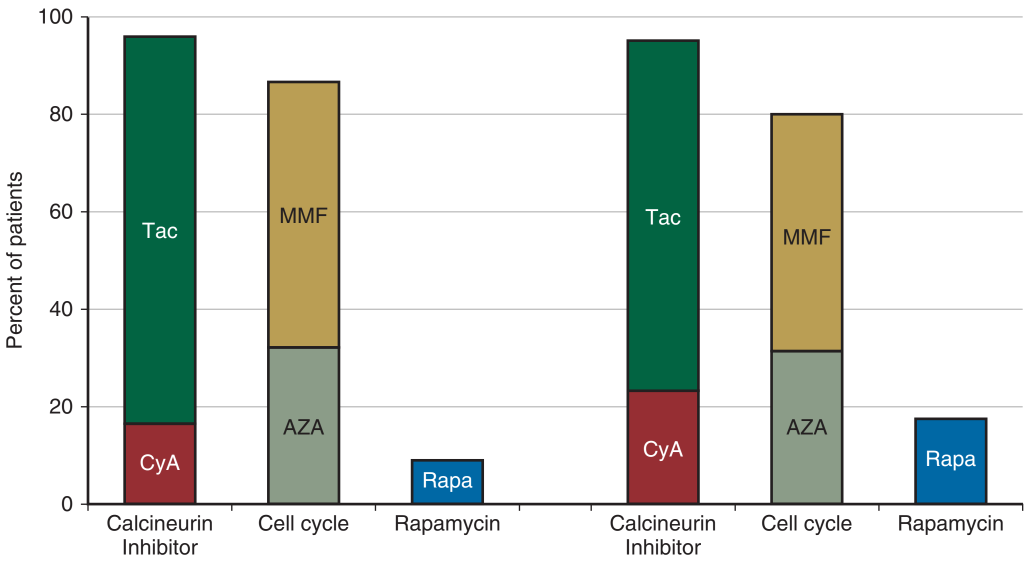

Figure 75-22 Adult lung recipients' maintenance immunosuppression drug combinations at time of follow-up (data for follow-up evaluations performed between January 2002 and June 2005). Conventional combinations analysis was limited to patients receiving prednisone. *AZA*, azathioprine; *Cy*, cyclosporine; *MMF*, mycophenolate mofetil; *Rapa*, rapamycin; *Tac*, tacrolimus.

no definitive evidence to suggest superior outcomes with these newer drugs.

MEDICAL COMPLICATIONS IN LUNG TRANSPLANT SURVIVORS

Lung transplant survivors are at risk for multiple medical complications related to their predisposing illness and toxicities resulting from chronic immunosuppression. The aim of long-term care in the transplant recipient revolves around prevention and early detection of commonly described posttransplantation medical illnesses.

NEUROMUSCULAR

Neuromuscular toxicity is a well-described complication of the calcineurin inhibitors. This complication is thought to be dose-dependent and presents with symptoms ranging from headache and tremors to seizures and confusion. The posterior leukoencephalopathy syndrome can result in cortical blindness from microvascular injury and encephalopathy. Myopathies are common, especially when the calcineurin inhibitors are used in combination with corticosteroids, presumably caused by direct mitochondrial toxicity. This is an important complication, because the major limiting factor in posttransplantation exercise capacity seems to be related to muscular dysfunction and inadequate mitochondrial activity, rather than to cardiopulmonary deficiency. In patients with seizures, treatment should start with reducing the dose of calcineurin inhibitor and adding an antiepileptic that does not interact with the immunosuppressant regimen.

OSTEOPOROSIS

As discussed earlier, osteoporosis is a relative contraindication to transplantation. Fractures occur commonly after

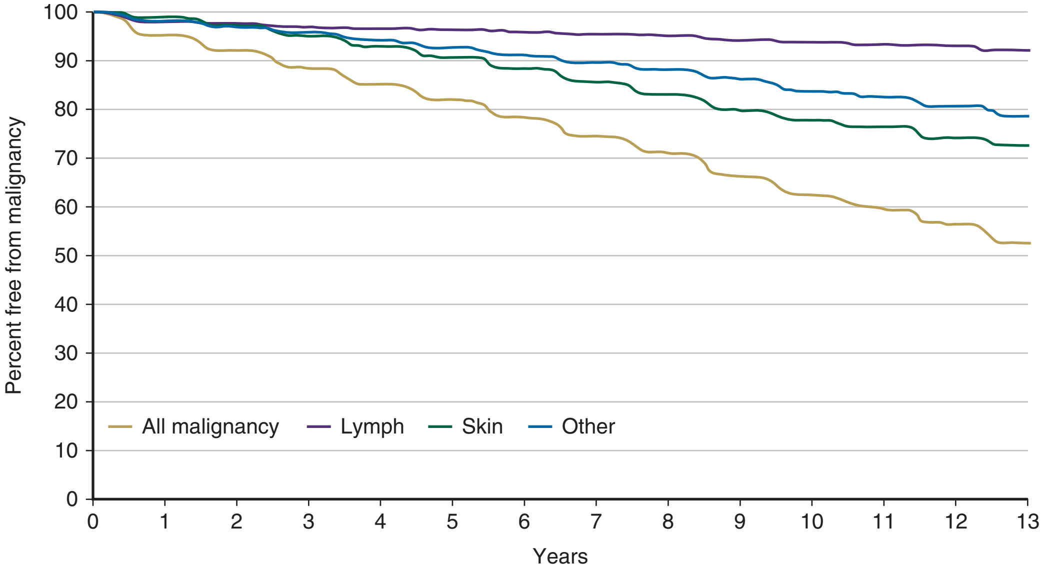

Figure 75-23 Freedom from malignancy for adult lung recipients (data for follow-up evaluations performed between April 1994 and June 2005).

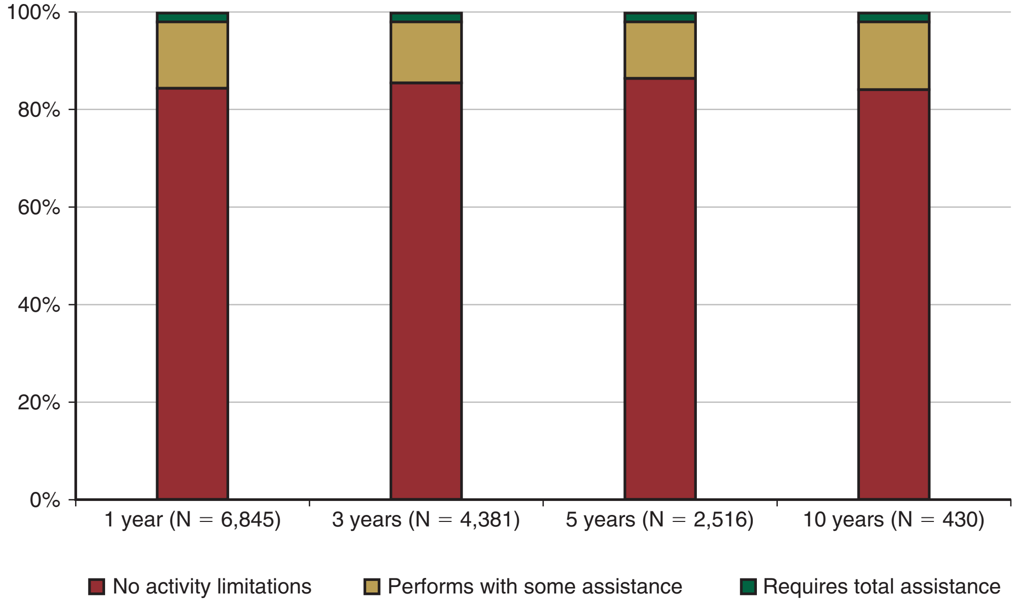

Figure 75-24 Adult lung recipients' functional status of surviving recipients (data for follow-up evaluations performed between April 1994 and June 2005).

transplantation and can be severely debilitating. Advanced age, poor nutrition, immobility, and smoking all contribute to bone demineralization. Corticosteroids and calcineurin inhibitors are known to increase bone resorption and to promote the development of severe osteoporosis. Many centers will treat patients at risk before transplantation with exercise, calcium supplementation, vitamin D, and antiresorptive agents such as the bisphosphonates to reduce the posttransplantation risk.

MALIGNANCY

Posttransplantation malignancy (Figure 75-23) frequently is seen after solid organ transplantation. The calcineurin inhibitors and azathioprine have been associated with a higher risk of cancer. Currently, a 10% incidence of tumor development is reported in 5-year survivors, with lymphoid and skin cancers accounting for a majority. Newer immunosuppressive agents, such as the mTOR inhibitors, seem to have antineoplastic properties; evidence that these agents lead to lower cancer risk or decreased mortality is lacking, however.

OTHER MEDICAL COMPLICATIONS AFTER TRANSPLANTATION

Acute and chronic nephrotoxicity is well described with use of the calcineurin inhibitors and is characterized by hyalinosis of afferent arterioles, vacuolization of proximal tubules, and focal areas of interstitial and glomerular fibrosis (Figure 75-24). Although renal dysfunction is rather common in 1-year survivors, renal failure requiring dialysis remains rare. Use of calcineurin inhibitors as well as corticosteroids also can lead to diabetes mellitus, hypertension, and dyslipidemia (Table 75-14).

Table 75-14 **Post-Lung Transplantation Morbidity in Adults**

	Follow-ups: April 1994–June 1999		Follow-ups: July 1999–June 2005	
Outcome	**Within 1 Year**	**Total Number with Known Response**	**Within 1 Year**	**Total Number with Known Response**
Hypertension	48.3%	(*N* = 3162)	53.2%	(*N* = 4735)
Renal dysfunction	22.2%	(*N* = 3088)	27.4%	(*N* = 4870)
Abnormal creatinine <2.5 mg/dL	12.5%		18.9%	
Creatinine >2.5 mg/dL	8.0%		6.7%	
Chronic dialysis	1.7%		1.8%	
Renal transplantation	0.0%		0.1%	
Hyperlipidemia	11.0%	(*N* = 3280)	23.9%	(*N* = 5064)
Diabetes	16.10%	(*N* = 3129)	26.9%	(*N* = 4800)
Bronchiolitis obliterans	10.7%	(*N* = 2817)	7.3%	(*N* = 4460)

Cumulative prevalence in survivors within 1 year after transplantation (follow-ups: April 1994–June 2005).

Section 15
SPECIAL CLINICAL CONDITIONS

Chapter 76
Pregnancy

Stephen E. Lapinsky

The pregnant patient who has pulmonary disease is unique because of altered maternal physiology, the occurrence of diseases specific to pregnancy, and the need to consider two patients in all therapeutic decisions. This chapter focuses on the changes in pulmonary physiology associated with pregnancy, certain pregnancy-specific disorders, and other pulmonary problems encountered in the pregnant patient.

PULMONARY PHYSIOLOGY

PHYSIOLOGIC CHANGES IN PREGNANCY

Hormonal changes in pregnancy affect the upper respiratory tract and cause airway hyperemia and edema resulting in symptoms of rhinitis. Estrogens are likely responsible for many of these effects because they produce capillary congestion and mucous gland hyperplasia. Changes to the thoracic cage result from both the enlarging uterus and the hormonal effects producing ligamentous laxity. The diaphragm is displaced cephalad by up to 4 cm, but the potential loss of lung capacity is partially offset by an increase in the anteroposterior and transverse diameters and by widening of the subcostal angle (**Figure 76-1**). Despite these anatomic changes, diaphragmatic function remains normal, diaphragmatic excursion is not reduced, and the maximum transdiaphragmatic inspiratory pressures that can be generated near term are similar to values generated by patients who are not pregnant. The changes in the chest wall return to normal within 6 months of delivery, although the costal angle may remain widened.

These changes in the thorax produce a progressive decrease in functional residual capacity (FRC) by 10% to 25% by term (**Figure 76-2**). Residual volume decreases slightly, but the major change is in expiratory reserve volume. These alterations are measurable as early as 16 to 24 weeks of gestation and progress to term. The increased diameter of the thoracic cage and the preserved respiratory muscle function allow the vital capacity to remain unchanged, and total lung capacity decreases only minimally. Measurements of airflow and lung compliance are not affected, but chest wall and total respiratory compliance are reduced in the third trimester because of the chest wall changes and increased abdominal pressure. Inconsistencies in results reported for diffusing capacity during pregnancy likely arise from the effects of anemia, variable changes in intravascular volume, and the increase in cardiac output. A small increase may be noted in early pregnancy with a subsequent decrease to normal values by term.

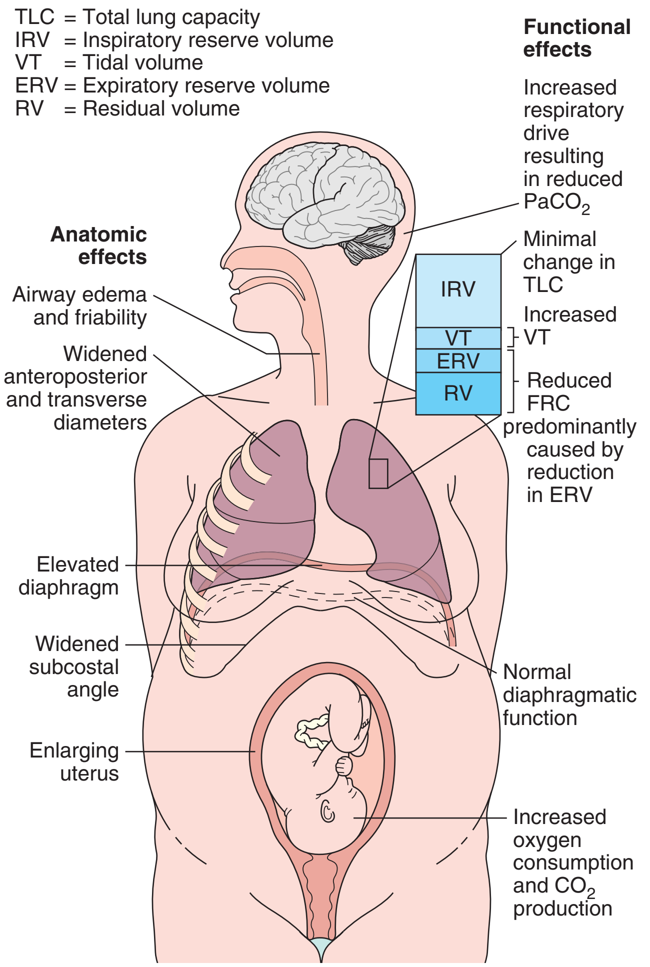
Minute ventilation increases greatly in pregnancy, beginning in the first trimester and reaching 20% to 40% above baseline at term (Figure 76-2), produced mainly by an increase in tidal volume of approximately 30% to 35%. These changes are mediated by the increase in respiratory drive that results from elevated serum progesterone levels. A respiratory alkalosis with compensatory renal excretion of bicarbonate results, with arterial carbon dioxide tension (PaCO_2) falling to 28 to 32 mm Hg and plasma bicarbonate falling to 18 to 21 mEq/L. Alveolar-arterial oxygen tension difference (PO_2[A–a]) is similar to nonpregnant values, and mean PaO_2 usually exceeds 100 mm Hg at sea level throughout pregnancy. Mild hypoxemia and an increased PO_2(A–a) may develop in the supine position because of airway closure, because FRC diminishes near term. One study suggests that shunt is normally increased in the third trimester to approximately 15% and is not changed significantly by posture. Oxygen consumption increases, beginning in the first trimester, and reaches 20% to 33% above baseline by the third trimester because of fetal demands and maternal metabolic processes. The combination of a reduced FRC and increased oxygen consumption lowers oxygen reserve, which renders the pregnant patient susceptible to the rapid development of hypoxia in response to hypoventilation or apnea.

During labor, hyperventilation increases, and tachypnea (caused by pain or anxiety) may result in marked respiratory alkalosis, augmented in some patients by volume depletion or vomiting. Alkalosis adversely affects fetal oxygenation by reducing uterine blood flow. In some patients, severe pain and anxiety may lead to rapid, shallow breathing with alveolar hypoventilation, atelectasis, and mild hypoxemia. Achieving adequate pain relief with narcotics or epidural analgesia blunts the ventilatory response and can correct the gas exchange abnormalities associated with active labor. The pregnancy-associated changes in lung function reverse significantly in the first 72 hours postpartum and return to baseline within a few weeks.

Changes occur to the pregnant woman's immune system, to facilitate tolerance to paternally derived fetal antigens. Some suppression of cell-mediated immunity occurs; maternal lymphocytes demonstrate a diminished proliferative response to soluble antigens and to allogeneic lymphocytes, and decreased numbers of T-helper cells have been documented. These effects are balanced by an intact or slightly enhanced humoral immune response. These alterations to maternal immunity result in a predisposition to more severe manifestations of some viral and fungal infections.

DYSPNEA IN PREGNANCY

Dyspnea is a common complaint in women who have otherwise normal pregnancies. It may develop in the first or second



TLC = Total lung capacity

trimester, and 70% of women complain of dyspnea by the third trimester. The mechanism is not clear but likely represents a normal awareness of increased ventilation; the physiologic increase in minute ventilation results in increased motor cortical stimulation of the respiratory center. The diagnosis of this benign condition is based on the presence of isolated dyspnea not usually affecting daily activities, the absence of associated symptoms, and the exclusion of other, pathologic conditions. Pregnancy also can be associated with increased exercise-induced dyspnea.

COMPLICATIONS AND DISORDERS OF PREGNANCY

PREGNANCY-SPECIFIC DISORDERS

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare obstetric complication (between 1 in 8000 and 1 in 80,000 live births) that carries a mortality rate of 10% to 86% and may account for 10% of maternal deaths. Amniotic fluid embolism is usually associated with labor and delivery, but it may also occur with uterine manipulations or uterine trauma or in the early postpartum period. The mechanism seems to involve amniotic fluid that enters the vascular circulation through endocervical veins or uterine tears. Particulate cellular contents and humoral factors in the amniotic fluid produce acute pulmonary hypertension, predominantly by causing vascular spasm (Figure 76-3). Acute

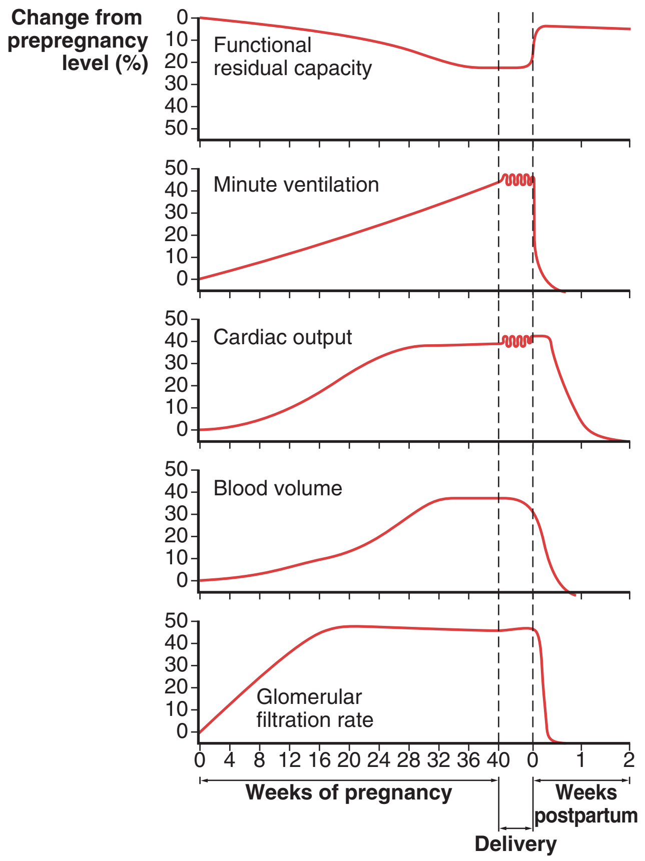

Figure 76-2 Physiologic changes in pregnancy. Shown are some of the physiologic changes that occur during pregnancy and the postpartum period. *(From Lapinsky SE, Kruczynski K, Slutsky AS: Critical care in the pregnant patient,* Am J Respir Crit Care Med *152:427–490, 1995.)*

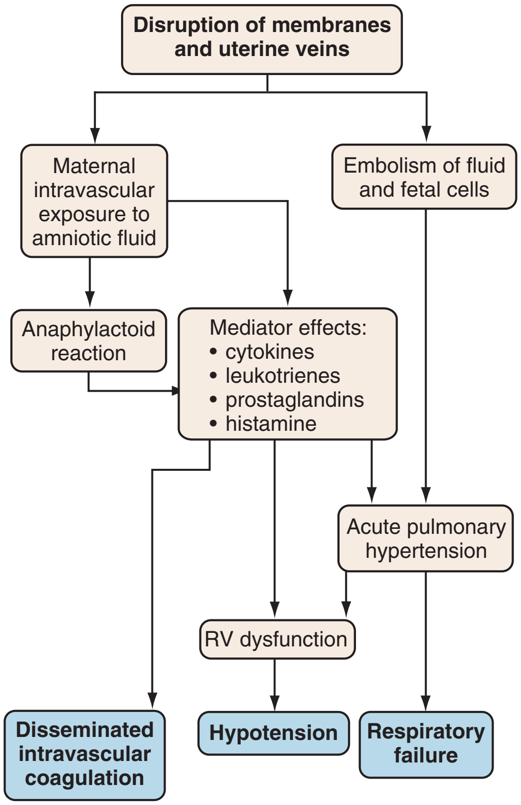

Disruption of membranes and uterine veins

• prostaglandins
• histamine
Acute pulmonary hypertension
RV dysfunction
Disseminated intravascular coagulation
Hypotension
Respiratory failure

Figure 76-3 Pathophysiology of amniotic fluid embolism: proposed pathophysiologic mechanisms for the development of circulatory shock caused by amniotic fluid embolism. *RV,* right ventricular.

right ventricular dysfunction results from the increased afterload and myocardial dysfunction mediated by humoral factors, associated with secondary left ventricular (LV) failure. The cardiovascular changes of amniotic fluid embolism may resemble those of anaphylaxis, and sensitivity to amniotic fluid contents may be responsible.

The clinical presentation usually involves the sudden onset of severe dyspnea, hypoxemia, and cardiovascular collapse, often accompanied by seizures. Less common presentations include hemorrhage caused by disseminated intravascular coagulation (DIC) and fetal distress. Up to one half of patients may die within the first hour, and cardiac arrest during this period is common.

The diagnosis of amniotic fluid embolism is usually made on the basis of observing the typical clinical picture. Fetal squames in a wedged pulmonary capillary aspirate have been used to confirm the diagnosis, but this is not a specific finding. Less invasive diagnostic tests, such as maternal serum zinc coproporphyrin or sialyl-Tn levels, have been investigated but are not currently in use. The differential diagnosis includes septic shock, pulmonary thromboembolism, abruptio placentae (placental abruption), tension pneumothorax, and myocardial ischemia.

Treatment and Prognosis

Treatment of the pregnant patient with amniotic fluid embolism involves routine resuscitative and supportive measures, with prompt attention to adequate oxygenation, mechanical ventilation, and inotropic support. No specific therapy has been shown to be effective, but some suggest a role for corticosteroids. In view of the inconsistent hemodynamic findings, invasive monitoring may be of value. Survivors of the initial resuscitation are likely to experience the complications of DIC or acute respiratory distress syndrome (ARDS). Neurologic damage caused by hypotension and hypoxemia is common.

Preeclampsia and Pulmonary Edema

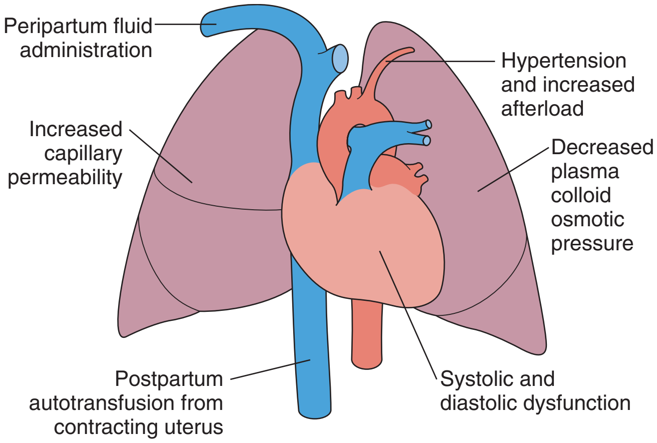
Pulmonary edema may rarely occur in association with preeclampsia (i.e., perhaps 3% of preeclamptic patients). The preeclamptic patient is usually volume-depleted, and pulmonary edema usually occurs in the early postpartum period, often associated with aggressive, intrapartum fluid replacement. Other factors that may contribute to the pathogenesis include reduced serum albumin, elevated LV afterload, and systolic and diastolic myocardial dysfunction (Figure 76-4). Increased capillary permeability may also occur, aggravated by concomitant conditions such as sepsis, placental abruption, or massive hemorrhage.

Pulmonary edema has been described in chronically hypertensive, obese, pregnant patients in whom preeclampsia develops. Diastolic LV dysfunction results from both the hypertension and the obesity, and pulmonary edema is precipitated by volume overload of pregnancy and hemodynamic stresses of preeclampsia.

Preeclampsia is characterized by hypertension, proteinuria, and peripheral edema, usually in the third trimester. The presentation of pulmonary edema is with acute respiratory distress in the preeclamptic patient, often in the early postpartum period.

Treatment and Prognosis

The standard approach is to restrict fluid, administer diuretics cautiously, and provide ventilatory support if necessary. Invasive monitoring may be useful if inotropic or vasodilator therapy becomes necessary, particularly in the patient with renal dysfunction. Aggressive diuresis must be avoided because filling pressures should not be reduced to the point of compromising cardiac output and reducing placental perfusion. Volume replacement may be necessary in preeclampsia, particularly if vasodilators are used, because these patients may be extremely volume-depleted. Excessive fluid replacement, however, may precipitate pulmonary or cerebral edema. The ultimate treatment of preeclampsia is delivery of the fetus.



Peripartum fluid administration
Hypertension and increased afterload
Increased capillary permeability
Decreased plasma colloid osmotic pressure
Postpartum autotransfusion from contracting uterus
Systolic and diastolic dysfunction

Figure 76-4 Pathophysiologic mechanisms responsible for the development of pulmonary edema in preeclampsia.

Tocolytic Pulmonary Edema

Beta-adrenergic agonists, as well as several other drugs, including nifedipine, indomethacin, atosiban, and magnesium sulfate, may be used to inhibit uterine contractions in preterm labor. Use of these agents has become less common, however, because a number of studies have demonstrated that tocolysis does not improve neonatal outcome. A complication of these drugs during pregnancy, particularly the β-agonists, is the development of pulmonary edema. The frequency of tocolytic-induced pulmonary edema varies from 0.3% to 9%. Postulated mechanisms include prolonged exposure to catecholamines causing myocardial dysfunction, increased capillary permeability, large volumes of intravenous (IV) fluid administration (often in response to maternal tachycardia), reduced osmotic pressure, and hypotension induced by β-adrenergic stimulation. Glucocorticoids are often administered in preterm labor to enhance fetal lung maturity and may compound fluid retention.

The clinical presentation is of acute respiratory distress with features of pulmonary edema. No specific features characterize tocolytic pulmonary edema. The diagnosis is a clinical one, made in the presence of acute pulmonary edema occurring in the appropriate clinical situation. The differential diagnosis includes cardiogenic pulmonary edema, amniotic fluid embolism, and other conditions (Table 76-1). Failure of the pulmonary edema to resolve in 12 to 24 hours requires a search for alternative causes.

Treatment and Prognosis

The tocolytic drug must be discontinued, whereupon pulmonary edema should resolve rapidly; additional treatment is supportive and includes diuresis. Early recognition and management should reduce the need for invasive hemodynamic monitoring and mechanical ventilation.

Peripartum Cardiomyopathy

Cardiac failure may occur in the absence of preexisting heart disease as a result of the hypertension of pregnancy or

Table 76-1 Acute Respiratory Distress Caused by Complications of Pregnancy and Labor

Disorder	Distinguishing Features
Amniotic fluid embolism	Cardiorespiratory collapse, seizures, disseminated intravascular coagulation
Pulmonary edema caused by preeclampsia	Hypertension, proteinuria
Tocolytic pulmonary edema	Tocolytic administration, rapid improvement with discontinuation
Aspiration pneumonitis	Vomiting, aspiration
Peripartum cardiomyopathy	Gradual onset, signs of heart failure
Venous thromboembolism	Evidence of deep venous thrombosis; radiologic investigations
Pneumomediastinum	Occurs during delivery; subcutaneous emphysema
Air embolism	Related to sexual intercourse or cesarean section; associated hypotension

peripartum cardiomyopathy. This idiopathic dilated cardiomyopathy presents in the last month of pregnancy or in the postpartum period. The diagnosis is made by demonstrating impaired LV function in the absence of other causes of cardiomyopathy. During labor and the early postpartum period, tachycardia and increased cardiac output may precipitate pulmonary edema. Pulmonary thromboembolic events are a common complication of this condition. Management is with diuretics and afterload reduction, bearing in mind that angiotensin-converting enzyme (ACE) inhibitors should not be used during pregnancy because of the development of fetal renal dysfunction. Anticoagulation is recommended in all patients. Other therapeutic interventions that have been used include intravenous immune globulin (IVIG) and bromocriptine. Recovery occurs in approximately half of patients within 6 months, but persistent or progressive cardiac failure develops in a significant proportion. Because mortality is 12% to 18% in the heart failure patients, cardiac transplantation may be considered.

Gestational Trophoblastic Disease

Pulmonary hypertension and pulmonary edema may complicate benign hydatidiform mole, caused by trophoblastic pulmonary embolism. This most often occurs during evacuation of the uterus, and the incidence of pulmonary complications is higher in later gestations. Molar pregnancy may be associated with *choriocarcinoma*, which can produce multiple, discrete pulmonary metastases and occasionally pleural effusions.

Ovarian Hyperstimulation Syndrome

Associated with administration of gonadotropins to stimulate ovulation for in vitro fertilization, the patient with ovarian hyperstimulation syndrome may present with gastrointestinal or respiratory symptoms. Increased capillary permeability results in bilateral pleural effusions and ascites, associated with intravascular volume depletion. Complications include respiratory compromise because of the effusions, shock and renal failure caused by the volume depletion, and pulmonary emboli. Treatment is supportive, with fluid resuscitation and drainage of effusions.

OTHER PULMONARY DISORDERS IN PREGNANCY

Asthma

Asthma affects 5% to 10% of the population and is therefore the most common pulmonary disorder in pregnancy. During pregnancy, the altered hormonal milieu may affect asthma control variably; patients may improve, worsen, or remain unchanged. Although pregnancy does not affect airflow in normal subjects, airway hyperreactivity in asthmatic subjects can be increased. Asthma severity usually returns to prepregnancy levels within 3 months postpartum.

The clinical features of asthma during pregnancy are the same as those in patients who are not pregnant. To differentiate from the dyspnea of pregnancy, objective assessment that uses pulmonary function tests to assess the degree of airflow limitation is essential. Gastroesophageal reflux (GER) is increased in both frequency and severity during pregnancy, and the symptoms of GER should be sought as a contributing factor.

Treatment and Prognosis

Management of the pregnant patient with asthma is similar to that in patients who are not pregnant and includes adequate monitoring, avoidance of precipitating factors, and patient education.

Although physicians may be reluctant to prescribe medications during pregnancy, poorly controlled asthma is potentially more dangerous for the fetus. Inhaled corticosteroids remain the mainstay of therapy, and are considered safe in pregnancy in moderate or low doses (Table 76-2). One study suggests a small increased risk of congenital malformation in women using high-dose therapy in the first trimester. The use of a spacer device is encouraged to reduce local side effects and systemic absorption. Although animal data suggest a small risk of cleft palate with systemic corticosteroid use, this has not been demonstrated in humans. Short courses of prednisone should be used to manage poorly controlled asthma when clinically indicated. Inhaled β-agonists seem safe and should be used as required for symptomatic relief. GER, a potentially preventable cause of worsening asthma, is frequently overlooked. Antireflux measures may greatly reduce asthmatic symptoms. Acute attacks are treated by ensuring adequate oxygenation, closely monitoring the fetus, and administering appropriate medications. Concerns over fetal effects of drugs should not cause physicians and patients to avoid use of effective pharmacologic therapy. Updated management algorithms are available through the Working Group on Asthma and Pregnancy of the National Asthma Education and Prevention Program (NAEPP).

Poor asthma control has been reported to increase the incidence of preterm birth, low birth weight, and perinatal mortality. Acute exacerbations may be associated with hypoxemia, which in turn may compromise the fetus.

Pulmonary Thromboembolic Disease

The incidence of venous thromboembolic disease related to pregnancy is 200 per 100,000 woman-years. The incidence is five times greater in the postpartum period than during pregnancy, and it remains an important cause of maternal mortality. Pulmonary embolism results from a hypercoagulable state associated with pregnancy, as well as from hormonally mediated venous stasis and local pressure effects of the uterus on the inferior vena cava (IVC). Pulmonary embolism occurs more frequently in the early postpartum period than during pregnancy, particularly after cesarean section.

Table 76-2 **Safety Classification of Asthma Therapy in Pregnancy**

Drug	FDA Class

Therapy	FDA Class*	Comments
Heparin	C	Bone demineralization after prolonged use
Low-molecular-weight heparin	B/C	Good evidence of safety
Warfarin	D/X	Teratogenic, central nervous system abnormalities and bleeding occur, although the risk appears low Sometimes used in second trimester
Alteplase (r-tPA)	C	Consider in acute, life-threatening situations

*See Table 76-2 for U.S. Food and Drug Administration classification of drug safety in pregnancy.

The presentation is similar to that in the patient who is not pregnant. However, the clinical diagnosis of deep venous thrombosis (DVT) and pulmonary embolism is notoriously inaccurate. An overwhelming predilection for DVT in the left leg in the pregnant patient results from anatomic factors.

Investigation of suspected pulmonary embolism follows a similar approach to that in the patient who is not pregnant, and the diagnosis must be pursued aggressively. Duplex ultrasonography is useful for the diagnosis of DVT, although venous Doppler can give false-positive results because of venous obstruction by the gravid uterus. Ventilation-perfusion scanning can be performed with less than 0.5 mGy (<50 mrad) exposure to the fetus and, if necessary, a computed tomography (CT) pulmonary angiogram may be performed with similarly low fetal exposure (Figure 76-5). Teratogenicity is generally thought to require exposure greater than 50 to 100 mGy (5-10 rad), but an increased incidence of childhood leukemia may occur with fetal radiation exposures of 20 to 50 mGy (2-5 rad).

The use of radiologic investigations during pregnancy remains a concern for the fetus. However, the risk perceived by pregnant women and their husbands usually far exceeds the actual risk, and it is important to allay these concerns. It is important to establish a diagnosis of pulmonary embolism because of the major implications if such a diagnosis is missed and the potential effects of unnecessary therapy on the health of mother and fetus.

Treatment and Prognosis

Warfarin therapy during the first trimester has been associated with an embryopathy, and central nervous system abnormalities have been described with second- and third-trimester exposure. Accordingly, warfarin is usually avoided (Table 76-3). The anticoagulant of choice is *heparin*, which does not cross the placenta, is not associated with adverse fetal outcome, and can be readily reversed. Low-molecular-weight (LMW) heparins do not seem to cross the placenta and are both safe and effective in pregnancy.

When administered with adequate precautions, streptokinase, urokinase, and tissue plasminogen activator (tPA) have been used successfully without major hemorrhagic complications or significant adverse effects on the fetus or placenta.

Nevertheless, use of these agents should be limited to life-threatening situations. When clinically indicated, an IVC filter can be placed transvenously, although there is some risk of dislodgment because of the dilated venous system and pressure effects during labor.

Women who have a known hypercoagulable state and those with a previous thromboembolism are at increased risk and should receive prophylaxis with anticoagulation throughout pregnancy.

Lower Respiratory Tract Infections

Lower respiratory tract infections are an infrequent occurrence but an important cause of indirect obstetric death. The pregnant patient is susceptible to the usual bacterial pathogens such as *Streptococcus pneumoniae, Haemophilus influenzae*, and *Mycoplasma pneumoniae* and is at increased risk of complications such as respiratory failure and empyema. Pregnant women are at increased risk of developing severe respiratory disease related to influenza, particularly the 2009 pandemic H1N1 strain. Less common infections such as varicella pneumonia and coccidioidomycosis may be associated with more severe disease than in nonpregnant patients. These effects are caused by subtle changes in cell-mediated immunity as a result of the pregnant state. *Pneumocystis jirovecii* (previously *P. carinii*) pneumonia may be seen in human immunodeficiency virus (HIV)–positive patients. Pregnancy does not seem to affect the course or incidence of reactivation of tuberculosis.

The clinical features of lower respiratory infection are similar to those in nonpregnant patients. Although dyspnea and increased minute ventilation are common in pregnancy, the respiratory rate is not significantly elevated by the pregnant state.

A chest radiograph is essential for the diagnosis of lower respiratory tract infections and must be considered in any pregnant woman who has a clinical presentation suggestive of pneumonia. Delayed radiography may be partly responsible for the increased morbidity in the pregnant patient population. Further diagnostic investigations include the usual microbiologic cultures, sputum microscopy, and serologic tests as indicated.

Treatment and Prognosis

Usual antibiotic guidelines may be followed, although tetracyclines should be avoided in pregnancy. Quinolones are usually avoided in pregnancy because of an association with arthropathy, but the risk seems to be low. Pregnant women should receive the influenza vaccine, and if disease occurs, treatment with oseltamivir is appropriate. Treatment of varicella pneumonitis is with acyclovir, which decreases mortality and has not been associated with fetal anomalies. Coccidioidomycosis is associated with an extremely high mortality rate, and disseminated disease should be treated with antifungal agents. *P. jirovecii* pneumonia requires treatment with trimethoprim-sulfamethoxazole with folate supplementation, as well as with corticosteroids, if indicated clinically. Although folic acid antagonists and sulfa drugs carry risks for the fetus, pentamidine is associated with higher risks for mother and fetus. Tuberculosis treatment is with isoniazid and rifampin (rifampicin), which have a low risk of adverse fetal effects, as well as ethambutol initially, until sensitivities are available. Pyrazinamide has been used in pregnancy and is recommended by some authorities.

Although pneumonia is associated with an increased risk of mortality, this is probably attributable to underlying diseases rather than to the pneumonia. Fetal complications may occur, as may preterm labor. Transplacental transmission of varicella-zoster virus (VZV) occurs infrequently (<5%) but can produce limb deformities and neurologic involvement. The nonimmune pregnant woman exposed to VZV should receive prophylaxis with VZV immunoglobulin within 96 hours of exposure, as well as acyclovir if clinical disease develops. Unlike the treatment of active disease, tuberculosis prophylaxis can usually be deferred until after pregnancy, except in the case of recent exposure or skin test conversion.

When investigating and managing lower respiratory tract infections, it is important to consider effects on the fetus (radiation exposure, drug toxicities), but necessary evaluations and interventions should not be avoided inappropriately.

Box 76-1 Causes of Acute Respiratory Distress Syndrome in Pregnancy

Nonspecific
Trauma
Drugs/toxins
Pancreatitis

Acute Respiratory Distress Syndrome in Pregnancy

The pregnant patient is at risk for development of ARDS from a number of pregnancy-associated problems (Box 76-1). Gastric acid aspiration is a particular risk because of the increased intraabdominal pressure, reduced lower esophageal sphincter tone, and supine position during delivery. Iatrogenic factors such as excessive fluid administration and tocolytic therapy may contribute, as well as reduced albumin level.

The clinical features are similar to those in the nonpregnant patient. The diagnosis is by the usual criteria of hypoxemia in the presence of diffuse pulmonary infiltrates and in the absence of LV failure. A detailed history is critical for identification of the underlying problem.

Treatment and Prognosis

There are no major differences in the management of pregnant patients who have ARDS compared with those who are not pregnant, other than the need for continuous assessment of the fetus. When administering pharmacologic therapy, it is critical to consider the effects on both the fetus and the mother. Ventilatory management includes consideration of the normal physiologic changes of pregnancy. Adequate maternal oxygen saturation is essential for fetal well-being. Alkalosis has an adverse effect on placental perfusion and should be limited. Acidosis seems to be reasonably well tolerated by the fetus. Fetal delivery may benefit both the mother and the fetus, but delivery to improve maternal well-being is not always successful. Epidural anesthesia may reduce the increased oxygen demand produced by uterine contractions.

Survival in the pregnant ARDS patient seems to be similar or better than that in the general population, possibly because of the young age of patients and the reversibility of many predisposing conditions. Specific causes of ARDS that pertain to pregnancy should be sought when assessing patients who have this syndrome. When women of childbearing age are seen with ARDS, they should be checked for pregnancy.

Pleural Disease

Although pleural effusions may accompany obstetric complications such as preeclampsia and choriocarcinoma, small, asymptomatic pleural effusions develop in a substantial proportion of women in the postpartum period. These result from the increased blood volume and reduced colloid osmotic pressure that occur in pregnancy, as well as from impaired lymphatic drainage caused by Valsalva maneuvers that occur during labor. Moderate-size effusions or the presence of symptoms should prompt a full clinical evaluation. Repeated expansion to total lung capacity with or without Valsalva maneuvers of labor may also cause *spontaneous pneumothorax* and *pneumomediastinum*, particularly in patients affected by predisposing conditions such as asthma. This diagnosis should be considered in patients who experience chest discomfort and dyspnea during or immediately after delivery.

Interstitial Lung Disease

Interstitial lung disease (ILD) is uncommon in pregnant women, because most cases occur in women beyond their childbearing years. When ILD is found in pregnant women, certain physiologic effects must be considered. A reduced diffusing capacity may lead to difficulty meeting the increased oxygen consumption requirements of pregnancy. Pulmonary hypertension carries increased risks because cardiac output increases during pregnancy. Minimal data exist on management and outcome of these patients, but restrictive lung disease seems reasonably well tolerated in pregnancy. Patients who have a vital capacity less than 1 L and those who have pulmonary hypertension should consider avoiding pregnancy. Lymphangioleiomyomatosis and systemic lupus erythematosus may worsen as a result of pregnancy.

Management of ILD involves careful assessment and monitoring of the pregnant patient's respiratory and cardiovascular status. Exercise intolerance is common, and patients may require supplemental oxygen early in pregnancy to avoid hypoxemic episodes, because these may be dangerous to the fetus. During labor, maternal effort should be limited and oxygen saturation must be monitored. Invasive hemodynamic monitoring may be indicated in the patient with pulmonary hypertension.

Obstructive Sleep Apnea

Pregnancy may be complicated by obstructive sleep apnea (OSA), with potential adverse effects for mother and fetus. Although upper airway narrowing has been documented in pregnancy, apnea and hypopnea are relatively uncommon because of the respiratory stimulatory effect of progesterone. Usually, OSA is confined to obese patients, perhaps precipitated by pregnancy-associated airway mucosal edema and vascular congestion. OSA may worsen in late pregnancy, coupled with the development of hypertension. The association between OSA and preeclampsia probably results from the generalized edema that occurs. Nocturnal hypoxemia may adversely affect the fetus, and poor fetal growth has been documented in these patients. Treatment with nasal continuous positive airway pressure (CPAP) is safe and effective. Snoring is not associated with fetal risk and is not a good marker for OSA in pregnant women.

Cystic Fibrosis

Advances in the management of patients who have cystic fibrosis (CF) have extended life expectancy into childbearing age. Although fertility is impaired, contraception and planned pregnancy should be considered in the management of these patients. Available data indicate that pregnancy does not increase mortality in patients with stable CF, but poor outcomes can occur in those affected by advanced disease. Those with a forced vital capacity less than 50% predicted and pulmonary hypertension before pregnancy are at greatest risk. Perinatal mortality is increased, related largely to preterm delivery that occurs spontaneously or to maternal CF complications. Management requires a multidisciplinary approach with careful attention to nutrition, glucose monitoring, and genetic counseling. Respiratory exacerbations require early aggressive therapy, with due consideration of the potential fetal toxicity of antibiotics (e.g., aminoglycosides, quinolones) and the altered maternal pharmacokinetics.

Gastric Aspiration

Gastric acid aspiration may occur during labor because of delayed gastric emptying, reduced lower esophageal sphincter tone, and the effects of increased intraabdominal pressure. The presentation is with cough, bronchospasm, and dyspnea, which can progress to ARDS. Prophylaxis with antacids, histamine-2 receptor antagonists, or proton pump inhibitors is often given before cesarean section.

Pulmonary Vascular Disease

Pregnancy in the patient with pulmonary hypertension is associated with an extremely high mortality rate, although this has improved somewhat in the past decade. The increased blood volume and cardiac output during pregnancy may precipitate right ventricular failure. LV filling may also be impaired as a result of ventricular interdependence. Hospitalization is recommended early in the third trimester, with close monitoring, anticoagulation, and oxygen therapy. The cardiovascular effects of labor pose a particular risk, and hemorrhage is poorly tolerated. Invasive hemodynamic monitoring may be of value. Successful pregnancy in these patients requires a multidisciplinary team approach in a referral center.

Pulmonary arteriovenous malformations expand during pregnancy because of the increase in blood volume and venous distensibility, which increases the likelihood of bleeding. Embolization and surgical management have been performed in pregnancy. The "idiopathic hemoptysis" described in pregnancy is related to hyperemia from dilated normal bronchial arteries.

CONTROVERSIES AND PITFALLS

Management of any pregnant patient is complicated by concerns for the fetus, particularly in regard to the effects of radiologic investigations and drug therapy. While not ignoring these effects, the clinician must not avoid investigations and drug treatment essential for maternal well-being. Good evidence exists regarding the risk of radiologic investigations, and most tests for respiratory diseases carry minimal risk to the fetus. Although there is a natural reluctance to prescribe drug therapy in pregnancy, good data and resources exist to identify the actual adverse effects of drug therapy; in many situations the benefit to the mother outweighs any risk to the fetus.

The respiratory medicine physician may be approached by a woman with severe lung disease asking about the risks of pregnancy. The evidence supporting such decisions is minimal, although women with pulmonary hypertension or marked obstructive or restrictive lung disease clearly are at increased risk of potentially fatal complications. Isolated case reports and individual experiences demonstrate the remarkable ability of women with severe disease to tolerate pregnancy, and the desire of a woman to have a baby should not be underestimated. In complex cases, referral to a center with multidisciplinary expertise is advisable.

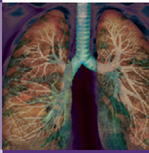
SPECIAL CLINICAL CONDITIONS



Chapter 77
Pulmonary Complications of Hematopoietic Stem Cell Transplantation

Rodrigo Cavallazzi • Rodney J. Folz

Hematopoietic stem cell transplantation (HSCT) refers to the transplantation of stem cells from bone marrow, growth factor–stimulated peripheral blood, and umbilical blood for the treatment of malignant and nonmalignant hematologic, autoimmune, and genetic diseases. Transplant recipients are at risk of serious complications as a result of pretransplant cytoreductive conditioning regimens, immunologic sequelae from engraftment of allogeneic lymphoid cells (which mediate graft-versus-host responses), the patient's immunosuppressed status, and infections secondary to immunosuppression. Autopsy studies show that pulmonary complications are responsible for more than 70% of deaths in HSCT recipients.

OVERVIEW OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

TYPES

Hematopoietic stem cell transplantation is classified as autologous, allogeneic, or syngeneic. In *autologous* HSCT, patients receive their own hematopoietic stem cells. In *allogeneic* HSCT, patients receive hematopoietic stem cells from a nonidentical sibling or unrelated matched donor. In *syngeneic* HSCT, patients receive hematopoietic stem cells from a genetically identical twin. The source of the donor hematopoietic stem cells can be bone marrow, peripheral blood, or umbilical cord blood. Because autologous and syngeneic transplants involve stem cells that are immunologically identical to the recipient, reactions between graft and host are avoided. In allogeneic transplants, mismatch between donor and recipient human leukocyte antigens (HLAs) mediate *graft-versus-host disease* (GVHD), which may lead to allograft rejection.

Factors that determine the type of transplant to be performed include the nature and stage of the underlying disease, the availability of a suitable donor, and the medical condition of the recipient. The advantages of allogeneic transplantation over autologous transplantation include a higher likelihood that the stem cell product is free of tumor contamination and graft-versus-host activity.

INDICATIONS

A survey from several countries found that the most common indications for HSCT are lymphoproliferative disorders (55%), leukemias (34%), solid tumors (6%), and nonmalignant disorders (5%). The *lymphoproliferative disorders* included plasma cell disorder, Hodgkin disease, and non-Hodgkin lymphoma. Autologous HSCT was slightly more common than allogeneic HSCT. For allogeneic HSCT, the most frequent malignant disease was acute myeloid leukemia (33%) and the most common nonmalignant disease, bone marrow failure syndrome (6%). For autologous HSCT, the most frequent indication was for a plasma cell disorder (41%); the most common nonmalignant indications included bone marrow failure, hemoglobinopathies, immune deficiencies, inherited diseases of metabolism, and autoimmune disorders.

CONDITIONING REGIMENS

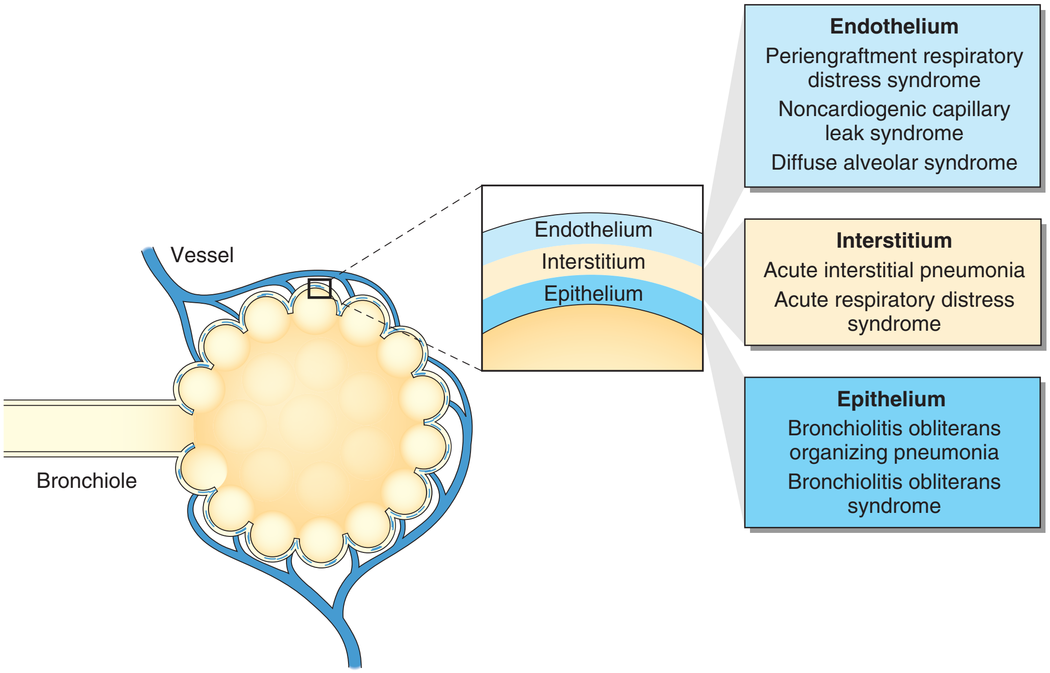
Before undergoing HSCT, patients receive a conditioning regimen with the goals of reducing the tumor burden (with malignancy), ablating the bone marrow, and suppressing the recipient's immune system, thereby allowing engraftment of stem cells. The three regimen types are myeloablative conditioning, reduced-intensity conditioning, and nonmyeloablative conditioning. This classification is based on the duration of cytopenia and the requirement for stem cell support. *Myeloablative* conditioning causes irreversible cytopenia, for which stem cell support is always necessary, whereas *nonmyeloablative* conditioning causes minimal cytopenia, for which stem cell support may not be needed. *Reduced-intensity* conditioning causes cytopenia of variable duration, and stem cell support should be given.

Conventional myeloablative conditioning regimens include cyclophosphamide and total-body irradiation (TBI) or busulfan. The more recent nonmyeloablative or reduced-intensity conditioning regimens have used fludarabine and reduced-dose alkylating agents or TBI. Although these less intensive regimens do not provide a strong cytoreductive effect, they allow engraftment of the donor stem cells with a subsequent potentially beneficial graft-versus-malignancy effect. The nonmyeloablative or reduced-intensity conditioning regimens are associated with reduced transplant-associated morbidity and lower incidence of pulmonary complications after transplantation.

Prophylaxis after allogeneic transplant to prevent GVHD usually involves methotrexate, cyclosporin, corticosteroids, or in vitro T cell depletion of the graft before infusion.

POSTTRANSPLANT PULMONARY COMPLICATIONS

Pulmonary complications after HSCT are common, with an incidence of 40% to 60% and with up to one third of recipients



Endothelium
Periengraftment respiratory distress syndrome
Noncardiogenic capillary leak syndrome
Diffuse alveolar syndrome
Vessel
Endothelium
Interstitium
Epithelium

Figure 77-1 Types and location of pulmonary complications after hematopoietic stem cell transplantation (bronchiolitis obliterans organizing pneumonia now called cryptogenic organizing pneumonia).

requiring intensive care after transplantation. Respiratory failure is the most common cause of critical illness, and pneumonia is the leading infectious cause of death after HSCT (Figure 77-1). Pulmonary complications can occur early or late in the posttransplant course, can have infectious and noninfectious etiologies, and can present with assorted radiographic findings. The pulmonary complications of HSCT also vary depending on the indication for, type of, and preparative regimen preceding HSCT.

Cellular interactions between graft and host cells are essentially eliminated with autologous transplantation, obviating the need for immunosuppression to prevent or treat GVHD. As such, autologous transplantation is associated with lower incidence of infection, particularly viral pneumonias or cytomegalovirus (CMV) pneumonitis, invasive fungal disease, and other opportunistic infections (e.g., toxoplasmosis), as well as late airflow obstruction defects.

RISK FACTORS FOR PULMONARY DISEASE

Relapse status at transplant and donor-recipient HLA mismatching or nonidentity are risk factors for pulmonary complications and mortality after HSCT (Box 77-1). Active phase of malignancy, age over 21 years, and receipt of HLA-nonidentical donor marrow are risk factors for respiratory failure after HSCT.

Abnormalities in pretransplant pulmonary function tests (PFTs) may be predictive of subsequent risk of pulmonary complications and mortality. Reduced diffusing capacity and increased alveolar-arterial oxygen gradient are independent risk factors for interstitial pneumonitis and also independently associated with increased early mortality after HSCT.

Patients with elevated levels of transforming growth factor beta (TGF-β) in plasma, TGF-α in bronchoalveolar lavage (BAL) fluid, and granulocyte-macrophage colony-stimulating factor (GM-CSF) in BAL fluid seem to be at increased risk for pulmonary complications. One study showed that elevated pretransplant TGF-β levels in patients with breast cancer undergoing autologous HSCT were associated with increased posttransplant risk of pulmonary toxicity and hepatic venoocclusive disease.

Box 77-1 Risk Factors for Pulmonary Complications After Hematopoietic Stem Cell Transplantation (HSCT)

Donor-recipient human leukocyte antigen mismatch
Relapse status
Active phase of malignancy
Age over 21 years
Pretransplant pulmonary function abnormalities
Reduced diffusion capacity
Increased alveolar-arterial oxygen gradient
Restrictive lung disease
FEV_1 <80% predicted
Elevated pretransplant cytokine levels (TGF-β, TGF-α, GM-CSF)
Allogeneic transplantation
Graft-versus-host disease and type of GVHD prophylaxis
Renal disease

Recipients of allogeneic transplantation have more infection complications than recipients of autografts, not only because of chronic immunosuppression, but also because GVHD itself causes an immunodeficient state by affecting the mucosal surfaces, the reticuloendothelial system, and bone marrow. These factors predispose allogeneic recipients to fatal viral pneumonias, multidrug-resistant bacteria, and invasive fungi. Similarly, bronchiolitis obliterans is almost exclusively seen after allogeneic HSCT.

GENETICS AND PULMONARY COMPLICATIONS

Some patients may be genetically predisposed to develop toxicity from the HSCT-related treatments. Indeed, recent studies suggest that certain genetic polymorphisms appear to play a role in the pathogenesis of diverse post-HSCT pulmonary complications. For example, having a polymorphism in the gene for angiotensin-converting enzyme (ACE) increases the likelihood of developing noninfectious pulmonary dysfunction after allogeneic HSCT. Polymorphisms in genes that code for proteins involved in stress-induced oxidant and antioxidant balance may be associated with acute lung injury after HSCT. In some patients, genetic polymorphisms may also be the basis for an increased susceptibility to infection after HSCT. For example, polymorphisms in the mannose-binding lectin gene in both the donor and the recipient are associated with increased risk of major infection.

Although still not routinely used in clinical practice, genetic screening may lead to a more refined prediction of risk for pulmonary complications in future patients undergoing HSCT.

TIME COURSE

Specific pulmonary complications associated with HSCT tend to occur in a relatively well-defined timeline. The timing and intensity of cytoreductive therapies and the resulting pattern of immune reconstitution influence the duration of these intervals.

Preengraftment

The preengraftment phase (0-30 days after transplant) is characterized by prolonged neutropenia and breaks in the mucocutaneous barriers. Accordingly, infectious complications are expected and primarily caused by bacterial and fungal infections. However, most pulmonary complications during this phase are noninfectious and related to regimen-related toxicities.

Early Postengraftment

The early postengraftment period spans days 30 to 100 after transplant and is characterized by persistent impairment in cellular and humoral immunity, in part determined by exogenous immunosuppression, GVHD, deficiency of immunoglobulins, and a loss of protective alveolar macrophages. During this period, neutropenia usually resolves, decreasing the risk of bacterial and fungal infections. The epidemiology of infectious etiologies thus changes to involve predominantly viral infections, especially CMV. With the routine use of antivirals, however, the incidence of posttransplant CMV pneumonia has decreased substantially. Noninfectious etiologies during this time include engraftment syndrome and delayed pulmonary toxicity syndrome.

Late Postengraftment

The late postengraftment period begins at day 100 after transplant. During this time, immune recovery and function are variable and depend on the type of HSCT. Autologous recipients recover more rapidly than allogeneic recipients. T cell responses to alloantigens return to normal, but immunoglobulin levels frequently remain depressed. Viral pathogens cause infections because of poor lymphocyte function, whereas inadequate cellular immunity results in bacterial and fungal pathogens. Noninfectious etiologies are primarily responsible for the pulmonary complications seen during this time, including chronic GVHD, drug-related pulmonary toxicity, bronchiolitis obliterans, restrictive or fibrotic lung disease, and cryptogenic organizing pneumonia (formerly BOOP).

Posaconazole
Trimethoprim-sulfamethoxazole (TMP-SMX)

HSCT, hematopoietic stem cell transplantation.

INFECTIOUS COMPLICATIONS

The overall risk of pulmonary infection in patients receiving HSCT depends on multiple risk factors, including chemotherapy and radiation-induced neutropenia, lung injury induced by the conditioning regimen, rejection in the form of GVHD, local disruption of host defenses, and intensity of pathogen exposure. In addition, HSCT recipients need to develop a functional immune system from donor-derived cells. Although the production of red blood cells, platelets, and granulocytes occurs soon after HSCT, production of lymphocytes, especially T cells, is considerably delayed. In the first 2 years after transplant, serious infections occur in 50% of otherwise uncomplicated transplants from histocompatible sibling donors and in 80% to 90% of matched unrelated donors or histocompatible recipients with GVHD.

Supportive care in the posttransplant period has changed the microbiology of pneumonia. Prophylactic administration of trimethoprim-sulfamethoxazole (TMP-SMX), antivirals, antifungals, and fluoroquinolones has decreased the incidence of *Pneumocystis jirovecii*, CMV, herpes simplex, and *Candida albicans* infections (Box 77-2). Resistant gram-negative and gram-positive bacteria, viruses, and other fungi remain important pathogens.

Bacterial Infections

Bacterial pneumonia is a major cause of morbidity and mortality in patients receiving HSCT. The first month after transplant is notable for pneumonias caused by usual pathogens. Bacterial pneumonia is frequently caused by *Staphylococcus* and *Streptococcus* spp. (24% and 13%, respectively, in one series) and gram-negative organisms, including *Pseudomonas*, *Klebsiella*, *Escherichia*, *Stenotrophomonas*, *Legionella*, *Acinetobacter*, *Serratia*, *Proteus*, *Enterobacter*, and *Citrobacter* spp. Other organisms include *Enterococcus* and rare anaerobes such as *Bacteroides* and *Fusobacterium* spp. Community pathogens emerge after the immediate posttransplant period. *Haemophilus influenzae* is the most common isolate, followed by *Streptococcus pneumoniae* and *Legionella* spp.

Fungal Infections

Fungal disease should be considered in patients with persistent focal radiographic abnormalities that do not respond to empirical antibiotic therapy and in those with nodular opacities on chest imaging, prolonged neutropenia, corticosteroid use, or a history of prior fungal infections.

Invasive aspergillosis is the leading cause of infectious death in HSCT patients, with a mortality of 70% to 90% in allogeneic recipients, despite treatment. The incidence of invasive aspergillosis in allogeneic recipients is 10% to 15%, with a bimodal distribution of cases. During the early preengraftment period that is characterized by profound neutropenia, both allogeneic and autologous recipients are at increased risk for invasive aspergillosis. Allogeneic patients experience a second period of vulnerability, however, during the postengraftment phase, coincident with the development of chronic GVHD, because of the need for augmented immunosuppression. The vulnerability to invasive aspergillosis is higher during the second period than during neutropenia.

Most cases of invasive aspergillosis are limited to the lungs, but sinus and central nervous system involvement can also be seen. Common presenting symptoms include cough and dyspnea, with fever absent in up to two thirds of patients. Concomitant pleuritic chest pain and hemoptysis are clues. Radiographic findings include single or multiple nodules, cavities, and consolidation. The infiltrates are usually focal. The *air crescent sign* describes a central nodule partially or fully surrounded by air, indicating a sequestrum of necrotic lung tissue that has separated from the surrounding parenchyma. The *halo sign* on computed tomography (CT) describes a rim of low attenuation representing edema or hemorrhage that surrounds a pulmonary nodule and is present in more than 90% of patients with neutropenia with invasive pulmonary aspergillosis. The diagnosis of invasive aspergillosis is confirmed by demonstration of fungal elements in diseased tissue and a positive culture result of a specimen from a normally sterile site. In clinical practice, however, biopsy is not usually feasible because of thrombocytopenia or coagulation deficits, and a presumptive diagnosis is often substantiated by high-resolution CT (HRCT) of chest, culture results, or indirect diagnostic tests, such as detection of galactomannan antigen in body fluids.

A randomized clinical trial comparing voriconazole with amphotericin B found that voriconazole led to better survival and improved responses of initial therapy. Therefore, *voriconazole* is recommended as the primary treatment for invasive aspergillosis. The voriconazole loading dosage is 6 mg/kg intravenously (IV) every 12 hours for 1 day, followed by 4 mg/kg IV every 12 hours. Although not the first choice, liposomal *amphotericin B* may be used as an alternative primary therapy. *Posaconazole*, 200 mg every 8 hours, is the first-choice agent for prophylaxis against invasive aspergillosis in high-risk patients, including HSCT recipients with GVHD.

Candida, *Cryptococcus*, and *Zygomycetes* (including *Mucor* and *Rhizopus*) are also important pathogens. The prevalence of invasive zygomycotic infection is 2% and bears a similar clinical course to that of *Aspergillus*. Zygomycetes are angioinvasive, leading to thrombosis, pulmonary infarction, and hemorrhage, with radiographs showing cavitation and halo sign. Mortality rates are high (60%-80%) despite treatment with amphotericin B and surgical resection.

The endemic fungi are encountered less frequently. *Histoplasma* and *Coccidioides* usually occur as reactivation of latent infection. *Blastomyces* usually represents primary disease. Other emerging fungal pathogens reported to cause pulmonary infections include *Fusarium* and *Scedosporium* spp.

Viral Infections

Viral infections, particularly CMV pneumonia, are an important cause of morbidity and mortality in the postengraftment period. *Cytomegalovirus pneumonia* has a nonspecific clinical presentation that includes fever, nonproductive cough, and hypoxia. Chest imaging demonstrates various abnormalities, most frequently bilateral interstitial opacities. A definitive diagnosis relies on demonstrating viral inclusion bodies in lung tissue (which can be difficult on transbronchial biopsy specimens) or detection of virus in BAL fluid by shell vial assay, polymerase chain reaction (PCR), or viral culture (in patients with a compatible clinical presentation). Mortality from CMV pneumonia in posttransplant patients exceeded 90% until the advent of combination therapy with ganciclovir and intravenous immune globulin (IVIG), which improved survival rates to as high as 70%. The use of prophylaxis has not only reduced the incidence but has also delayed the onset of disease, with more CMV infections now occurring 100 days after transplant.

Prophylactic regimens have taken two approaches: (1) universal prophylaxis to all high-risk patients for a defined period after engraftment and (2) preemptive treatment of patients only after detection of subclinical viremia by PCR assay. Both strategies reduce the risk of early CMV disease and are accepted practice guidelines. Seronegative patients who underwent allogeneic transplant from seropositive donors are at highest risk for CMV pneumonia.

The infection pattern of respiratory viruses in HSCT recipients is similar to that in the general population; however, HSCT recipients are more likely to develop lower respiratory tract infection, with mortality of 50% to 70%. Respiratory viruses classically recognized as causing disease in both immunocompetent and immunocompromised individuals include respiratory syncytial virus (RSV), parainfluenza, and influenza. New detection techniques have led to increasing identification of other respiratory viruses, such as human coronavirus, human metapneumovirus, human bocavirus, and human rhinovirus.

In a large prospective study, the 2-year incidence of a first episode of a viral respiratory infection was 29% in recipients of allogeneic HSCT and 15% in recipients of autologous HSCT. The most commonly isolated respiratory viruses were influenza A/B, human RSV, and human metapneumovirus.

Respiratory syncytial virus usually causes an upper respiratory infection, which may progress to fatal pneumonia in the immunocompromised patient. Late airflow obstruction has also been associated with RSV infection. Untreated, RSV pneumonia has a poor prognosis, with mortality approaching 80%. Treatment includes aerosolized *ribavirin;* other agents may be added, although a beneficial effect of concomitant therapy is not well established. Concomitant therapy includes IVIG, RSV-specific immunoglobulin, or palivizumab. Early initiation of treatment appears to be fundamental for the success of antiviral therapy. The role of preemptive therapy in the presence of isolated upper respiratory tract RSV infection is not well defined.

Adenovirus is an uncommon cause of pneumonia and can be isolated in 3% to 5% of patients after HSCT. The incidence is higher in children. It affects the upper and lower respiratory tracts, as well as the gastrointestinal and genitourinary systems. Infection usually develops within the first 3 months of transplantation, with a presentation that might include pharyngitis, tracheitis, bronchitis, pneumonitis, enteritis, hemorrhagic cystitis, or disseminated disease. Mortality with pulmonary involvement may exceed 50%. Cidofovir is used for preemptive (positive viremia despite absence of symptoms) and therapeutic treatment. Some centers have successfully used adenovirus-specific cytotoxic T cells for treatment.

Human metapneumovirus is an RNA paramyxovirus that causes infection in up to 5% of HSCT recipients. Patients usually present with upper respiratory tract symptoms but may also develop pneumonia. The role of antiviral therapy has not been defined in this infection.

Influenza types A and B can cause infection in both immunocompetent and immunocompromised patients, with type A being the most common. The 2009 influenza pandemic was caused by a novel H1N1 influenza A virus, a reassortment of classic swine H1N1, avian Eurasian swine H1N1, and North American human H2N2. Infection by novel H1N1 is characterized by severe disease in patients with specific risk factors, which include immunocompromised status. A cohort study from two medical centers found that HSCT recipients infected with novel H1N1 develop lower respiratory infection in 52% of the cases and have a 30-day mortality of 22%. Zanamivir and oseltamivir are neuraminidase inhibitors used to treat influenza types A and B. Amantadine and rimantadine are adamantanes, which are used only for influenza type A.

Other viral infections include herpes simplex virus (HSV), varicella-zoster virus (VZV), and human herpesvirus (HHV) types 6 and 7. HSV was a common cause of infection in HSCT recipients but incidence has been greatly reduced by acyclovir prophylaxis. HHV-6 has been associated with the idiopathic pneumonia syndrome. Epstein-Barr virus (EBV) infections usually manifest as posttransplant lymphoproliferative disorder.

Pneumocystis Pneumonia

The incidence of *Pneumocystis jirovecii* pneumonia (formerly *P. carinii* pneumonia, PCP) has been greatly reduced by TMP-SMX prophylaxis. Prophylaxis is recommended from time of engraftment to 6 months after transplant in all allogeneic recipients and indefinitely for those on augmented immunosuppressive therapy and those with chronic GVHD. *P. jirovecii* pneumonia presents approximately 60 days after transplantation with cough, dyspnea, fever, and bilateral interstitial and alveolar infiltrates on chest radiography. Diagnostic yield of BAL is almost 90%. Despite TMP-SMX treatment, mortality can be as high as 89% for *P. jirovecii* infections occurring within the first 6 months after transplant versus 40% for late-onset infections.

NONINFECTIOUS COMPLICATIONS

Idiopathic Pneumonia Syndrome

Idiopathic pneumonia syndrome (IPS) refers to a form of severe lung injury in which infectious etiologies, cardiac dysfunction, acute kidney injury, and iatrogenic fluid overload have been excluded. The syndrome encompasses several entities with varying clinical presentation. The heterogeneous clinical manifestations reflect the many lung insults underlying the pathogenesis of IPS, including toxic effects of HSCT conditioning regimens, immunologic cell-mediated injury, and inflammatory cytokines.

The incidence of IPS varies between 2.2% and 15% after allogeneic HSCT; the lower incidence is observed with nonmyeloablative conditioning regimens. The median time of onset for IPS is 22 days after HSCT (range, 4-106 days). There are reports of IPS following autologous HSCT, but it is predominantly seen after allogeneic HSCT. Risk factors for IPS include conventional conditioning regimens, older age, diagnosis of acute leukemia or myelodysplastic syndrome, development of severe acute GVHD, and high-dose TBI.

The insight obtained from animal models has stimulated the classification of the entities under the term *idiopathic pneumonia syndrome* according to the primary anatomic site of cellular damage: interstitial tissue, vascular endothelium, or airway epithelium (see Fig. 77-1). For example, in *interstitial* type of injury, there are increased numbers of cytotoxic T lymphocytes and cells expressing B7 family costimulatory ligands in the alveolar and interstitial spaces. In *vascular endothelium* type of injury, there are injured endothelial cells, and in *airway epithelium* type of injury, injured type II alveolar epithelial cells. This classification reflects complex interactive mechanisms with a pathogenic role attributed to several factors, including increased soluble inflammatory mediators (e.g., tumor necrosis factor alpha), increased host flora–derived lipopolysaccharide, enhanced oxidative stress, depletion of pulmonary surfactant, donor-derived T cell effectors, host antigen-presenting cells, donor accessory cells, and leukocyte recruitment to the lung.

Treatment of the HSCT patient with IPS includes supportive care and, more recently, the combination of corticosteroids. The use of subcutaneous etanercept has been associated with a high clinical response rate in a recent series.

Pulmonary Toxicity

In the immediate posttransplant period, pulmonary toxicity from prior chemo/radiotherapy or the pretransplant conditioning regimen may manifest as fever, dyspnea, cough, hypoxemia, and patchy or diffuse mixed interstitial and alveolar infiltrates on chest radiography. No prospective studies document the efficacy of steroids in these patients, but in clinical practice, prednisone (1-2 mg/kg/day) is used to treat lung toxicity once infection has been excluded.

Pulmonary Edema

Acute pulmonary edema is a complication that tends to occur early, typically in the second week after HSCT. Patients who develop pulmonary edema have fluid retention, as demonstrated by weight gain and a positive fluid balance in the first weeks after HSCT. The fluid retention correlates with left ventricular (LV) end-diastolic diameter measurements by echocardiography. These findings underline the importance of increased LV preload with subsequent elevation in LV end-diastolic pressure and increase in the capillary hydrostatic pressure in the pathophysiology of pulmonary edema after HSCT. Patients may also have underlying cardiac dysfunction secondary to previous treatment with chemotherapeutic agents and chest irradiation.

Noncardiogenic pulmonary edema may result from conditions such as drug-induced pulmonary toxicity, blood product transfusion, and hepatic venooclusive disease.

Diffuse Alveolar Damage

Diffuse alveolar damage is the histologic expression of acute lung injury and acute respiratory distress syndrome. It is therefore the end result of different disease processes, typically sepsis or drug toxicity. The histologic features vary according to the phase: exudative (first week) and organizing. In the exudative phase the histologic analysis reveals intraalveolar edema, interstitial widening, and hyaline membranes. In the organizing phase there is somewhat uniform fibrosis and prominent type 2 pneumocyte hyperplasia.

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) occurs in approximately 5% of autologous and allogeneic recipients. Risk factors include high-dose chemotherapy received before transplant, irradiation, and advanced age. Rapid immune system reconstitution has also been theorized to contribute to DAH. Neutrophil influx into the lung may accentuate the injury and precipitate hemorrhage. The typical symptoms are dyspnea and hemoptysis. Cough and fever may also be present. Although highly suggestive of DAH in the appropriate clinical setting, hemoptysis is not always present. Patients usually are seen during the periengraftment period within the first month after transplantation, but up to 42% of patients with DAH are seen late, after day 30.

Diagnostic criteria proposed to diagnose DAH include alveolar injury, evident as diffuse lung infiltrates or increased alveolar-arterial oxygen gradient; absence of pulmonary infection; BAL fluid with increasingly bloodier return from three separate subsegments; or hemosiderin-laden macrophages at 20% or higher. The radiographic findings of DAH are often nonspecific and include an interstitial or alveolar pattern, usually of bilateral distribution and sparing the peripheral lung areas.

The mainstay of treatment of the HSCT patient with DAH is systemic steroid therapy, which should be instituted promptly. A reported regimen is methylprednisolone, 125 to 250 mg every 6 hours for 5 days, followed by a slow taper over 2 to 4 weeks.

Engraftment Syndrome

Engraftment syndrome is a clinical entity that occurs more often after autologous HSCT but can also follow allogeneic HSCT. A characteristic feature is the development of the syndrome within 96 hours of engraftment. The etiology is unclear but may be attributed to increased cytokine release and neutrophil degranulation during engraftment. The main clinical manifestations of engraftment syndrome include fever, erythrodermal rash, and noncardiogenic pulmonary edema. Patients may also present with hepatic dysfunction, renal insufficiency, weight gain, and transient encephalopathy. Treatment includes supportive care and steroids. For mild cases, steroids may not be warranted.

Delayed Pulmonary Toxicity Syndrome

Delayed pulmonary toxicity syndrome refers to pulmonary toxicity caused by chemotherapy that occurs in patients who undergo autologous HSCT. This syndrome has been associated with regimens containing carmustine and cyclophosphamide. It most often presents between 6 weeks to 3 months after HSCT. It has distinct features that allow the differentiation from idiopathic pneumonia syndrome. For example, delayed pulmonary toxicity syndrome is characterized by high incidence, low mortality, and significant steroid responsiveness. Symptoms include dyspnea, nonproductive cough, and occasional fever. The radiographic abnormalities are nonspecific and do not always correlate with symptoms or worsening pulmonary function. The most common abnormalities on CT scan include ground-glass opacities and mixed linear-nodular opacities. PFTs show decreased diffusion capacity (DLCO), and forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and total lung capacity (TLC) may also be decreased but usually to a lesser extent. Lung biopsy shows alveolar septal thickening, interstitial fibrosis, and type 2 pneumocyte hyperplasia, all consistent with drug toxicity. Treatment consists of steroids.

Interstitial Pneumonitis or Interstitial Lung Disease

Interstitial pneumonitis or interstitial lung disease (ILD) manifests with diminished DLCO and TLC. It can occur at virtually any time after transplantation, with many patients remaining asymptomatic. The pulmonary function changes seen in ILD are usually secondary to treatment with conditioning regimens, particularly those containing carmustine.

Bronchiolitis Obliterans

Bronchiolitis obliterans (obliterative bronchiolitis) is a complication that follows allogeneic HSCT. Rarely, it may also occur after autologous HSCT. The incidence of bronchiolitis obliterans in different reports has ranged from 0% to 48%. Risk factors for obliterative bronchiolitis include chronic GVHD, older age, presence of obstructive disturbance before HSCT, viral infections of the respiratory tract, and busulfan-based conditioning regimens. The close association with GVHD has led some experts to claim that bronchiolitis obliterans may indeed represent the lung manifestation of GVHD.

The activation of donor-derived T lymphocytes plays an important role in the pathogenesis of bronchiolitis obliterans. T cells target the recipient epithelial cells in the bronchioles, leading to an inflammatory reaction. Toll-like receptor–4 signaling in donor-derived hematopoietic cells also appears to be an important factor in causing alloimmunity. Obliterative bronchiolitis tends to occur late, typically more than 100 days after HSCT. The most common symptoms are dry cough, dyspnea, and wheezing. The physical examination may reveal decreased breath sounds, wheezing, and inspiratory squeaks. Furthermore, physical examination often reveals signs of GVHD outside the lung such as skin manifestations. In a minority of patients, there are no respiratory manifestations, and the diagnosis is established by PFTs. The chest radiograph is usually normal, although patients with advanced disease may have signs of hyperinflation, bronchiectasis, and areas of scarring. The HRCT scan is more sensitive for all the previously mentioned abnormalities and valuable in showing air trapping and mosaic attenuation during expiration. PFTs show an obstructive pattern, with FEV_1/FVC ratio less than 0.7 and a decrease in FEV_1 greater than 20% from pretransplant value.

Treatment of the HSCT patient with bronchiolitis obliterans involves corticosteroids, such as prednisone at 1 to 1.5 mg/kg daily, and intensification of immunosuppressive therapy.

Pulmonary Venoocclusive Disease

Pulmonary venoocclusive disease (PVOD) is characterized by *obliterative fibrotic vasculopathy*, which affects mainly the small branches of the pulmonary venous circulation. PVOD may be idiopathic or secondary to another disease. Diseases and risk factors associated with development of PVOD include exposure to chemotherapeutic agents (e.g., carmustine, mitomycin C, bleomycin), autologous and allogeneic HSCT, solid-organ transplantation, radiotherapy, and autoimmune diseases. Patients are seen several months after transplantation with progressive dyspnea on exertion and fatigue. They may also have pleural effusions with right upper quadrant tenderness and ascites. Chest radiography reveals interstitial edema. Abnormalities on HRCT scan include ground-glass opacities with centrolobular distribution, septal thickening, and mediastinal lymphadenopathy.

The diagnosis of PVOD is definitively established by histologic analysis of lung biopsy specimens, but lung biopsy is not indicated because of the high mortality risk. Histologic analysis reveals fibrosis of the venules and small veins in the interlobular septae of the pulmonary circulation, with resultant intraluminal thrombosis. The pulmonary arteries may display medial hypertrophy and eccentric intimal fibrosis. Right-sided cardiac catheterization typically reveals a precapillary pattern of pulmonary hypertension, with an increase in the mean pulmonary artery pressure and normal-range pulmonary capillary wedge pressure. Pulmonary vasodilators can exacerbate the pulmonary edema. Anecdotal reports describe PVOD patient response to high-dose corticosteroids.

Posttransplant Malignancy and Lymphoproliferative Disorder

Posttransplant lymphoproliferative disorder is a term used for different B cell hyperproliferative states that may have benign or malignant behavior. It may follow both solid-organ transplantation and allogeneic HSCT. The lymphoid proliferation is characterized by T cell dysfunction, which results from the conditioning regimen and presence of Epstein-Barr virus. The T cell dysfunction leads to a proliferation of EBV-infected B lymphocytes. Incidence varies from 0.6% to 10%. Risk factors for this disorder include HLA-mismatched donor, T cell depletion of the graft, anti–T cell agents, older age of donor, splenectomy, and mismatch in CMV or EBV status between recipient and donor.

The time from transplantation to development of posttransplant lymphoproliferative disorder is 70 to 90 days. Patients are usually seen within the first 6 months after transplant with lymph node, liver, and spleen involvement, often with relapse with the original malignancy (especially lymphoma) or with secondary lymphomas. Lung involvement is seen in 20% of patients. Treatment consists of reduction in immunosuppressive therapy. Prophylactic administration of rituximab during HSCT has been proposed to prevent posttransplant lymphoproliferative disorder in high-risk patients.

Cryptogenic Organizing Pneumonia (Bronchiolitis Obliterans Organizing Pneumonia)

Cryptogenic organizing pneumonia (COP), formerly bronchiolitis obliterans organizing pneumonia (BOOP), is an inflammatory condition that follows allogeneic and autologous HSCT. The onset of COP varies but usually occurs about 100 days after HSCT. It can be the residue of treated CMV pneumonitis, related to chronic GVHD, or can be idiopathic. Patients present with dry cough, dyspnea, and fever. Physical examination may reveal crackles and inspiratory squeaks. Chest HRCT findings include patchy consolidation, ground-glass attenuation, and randomly distributed nodules. Treatment includes steroid therapy, such as oral prednisone at an initial dose of 1 mg/kg daily, then tapered over 3 to 6 months.

Respiratory Failure

Recipients of HSCT have an overall rate of intensive care unit admission of 15.7%, and the most common cause for ICU admission is respiratory failure followed by shock secondary to sepsis. Independent risk factors for the requirement of assisted mechanical ventilation include older age, active malignancy at transplantation, and donor-recipient HLA mismatch. A review demonstrated that the pooled mortality in HSCT recipients requiring invasive mechanical ventilation is 86.4%. Noninvasive positive-pressure ventilation in select patients with reversible acute respiratory failure is used because observational studies show a survival benefit in HSCT recipients and patients with cancer. In critically ill HSCT recipients, it is also important to comply with the current evidence-based precepts of critical care medicine. For example, in patients with acute respiratory syndrome undergoing mechanical ventilation, a tidal volume of 6 mL/kg of ideal body weight should be targeted.

Other Noninfectious Complications

The term *pulmonary cytolytic thrombi* describes a vasculopathy that occurs in pediatric allogeneic HSCT recipients. It is characterized by an obliterative arteriopathy, occlusive vascular lesions, and hemorrhagic infarcts. This entity can resolve spontaneously without specific therapy. *Pulmonary alveolar proteinosis* has also been reported as a reversible cause of respiratory failure after allogeneic HSCT for acute leukemia.

DIAGNOSTIC EVALUATION

In the diagnostic evaluation of the HSCT patient, information should be obtained on the duration of the pulmonary complication, the radiographic abnormalities, and individual patient factors, such as exposure to toxic drugs, a history of receiving chest radiotherapy, current and previous immunosuppressive regimens and infection prophylaxis, CMV status of donor and recipient, and history of previous opportunistic invasive fungal disease. Useful information may be obtained from PFTs, sputum examination, chest imaging, and serologic studies.

PATTERNS ON IMAGING

The initial imaging evaluation involves a chest radiograph, which can be normal in 15% of symptomatic patients with proven infiltrative lung disease. On the more sensitive chest CT, different patterns may suggest specific disease processes; for example, nodular infiltrates are typical of fungal infections. *Nocardia* and *Cryptococcus* also may present as nodular masses. *Focal infiltrates* usually reflect infectious processes. Noninfectious processes presenting as focal infiltrates include pulmonary emboli, acute radiation pneumonitis, and carcinoma. *Diffuse infiltrates* are nonspecific but often represent pulmonary edema in the preengraftment phase and infections after engraftment. *Pleural effusions* suggest bacterial, mycobacterial, or nocardial infections as well as noninfectious conditions such as pulmonary edema, hepatic venoocclusive disease, pulmonary infarction, and malignancy.

PULMONARY FUNCTION TESTS

Pulmonary function tests should be obtained before HSCT, after transplant in symptomatic patients, and at regularly scheduled intervals in high-risk individuals. Pretransplant abnormalities in DLco and alveolar-arterial oxygen difference are independent risk factors for interstitial pneumonitis and death. After transplant, typical PFT abnormalities include declining lung volumes, deceasing DLco, and worsening airflow limitations.

SEROLOGIC STUDIES

The presence of galactomannan, a cell wall component released by *Aspergillus* spp., in serum indicates invasive aspergillosis, as detected by enzyme-linked immunosorbent assay. Using a cutoff optical density of 0.5, the test has a sensitivity of 97.4%, specificity of 90.5%, positive predictive value of 66.1%, and negative predictive value of 99.4%. A galactomannan assay for the diagnosis of invasive aspergillosis has also been evaluated in BAL fluid. Using a cutoff optical density of 0.5, the test showed sensitivity of 86% and specificity of 89%.

An elevated level of (1,3)-β-D-glucan in serum is typically associated with invasive aspergillosis and invasive candidiasis but is not specific for a particular fungal infection.

Newer diagnostic techniques have allowed not only a more accurate diagnosis of usual viral respiratory infections but also the detection of emerging viruses that were previously undetected. Nasopharyngeal swab assays employing multiplex PCR can detect up to 20 different respiratory virus types or subtypes in a single rapid test.

Determining CMV serologic status of both recipient and donor is essential in pretransplant screening. The serologic status of the recipient as opposed to the donor is the primary determinant for CMV conversion. A shell vial culture with monoclonal antibody to p72 requires only 48 hours, and tests for antigenemia are rapid, standardized, semiquantitative, and inexpensive. Nucleic acid amplification by PCR on DNA extracted from infected leukocytes also allows rapid diagnosis, detecting infection 2 weeks before viral cultures become positive and 1 week before positive antigenemia, and is highly sensitive.

CONTROVERSIES AND PITFALLS

Bronchoscopy with BAL has the potential to identify the cause of acute respiratory failure in HSCT patients; however, it also carries risks, especially in hypoxemic patients. The role of bronchoscopy was prospectively evaluated in a multicenter observational study in which cancer patients or HSCT recipients with acute respiratory failure received bronchoscopy with BAL, as well as noninvasive diagnostic tests. Noninvasive tests had a diagnostic yield of 66.7%, and BAL bronchoscopy, 50.5%. Although the only investigation that provided a diagnosis in one third of the patients, bronchoscopy with BAL was associated with respiratory deterioration in half the nonintubated patients. Thus, although the routine use of bronchoscopy in HSCT recipients with acute respiratory failure remains controversial, in select patients, bronchoscopy may provide the only means for accurately determining the etiology of lung disease.

Transthoracic needle aspiration under CT or fluoroscopic guidance has a high sensitivity (70%) for detecting pulmonary complications in HSCT patients, with the most common findings being infection and malignancy. However, pneumothorax is also a common complication and may require chest tube placement.

If no diagnosis is made with either bronchoscopy or transthoracic needle aspiration, surgical lung biopsy by either open thoracotomy or a video-assisted thoracoscopic approach may be considered next. Although surgical lung biopsy has a sensitivity of 60% to 80%, the procedure may be associated with worse outcomes and thus should be recommended primarily for hematopoietic stem cell transplant recipients whose test results likely will significantly alter their management.

Section 15
SPECIAL CLINICAL CONDITIONS

Chapter 78
Hepatic and Biliary Disease

Aynur Okcay • Michael J. Krowka

The pulmonary consequences of liver disorders can be classified according to whether they predominantly affect the pleural space, the lung parenchyma, or the pulmonary circulation. Unique pulmonary abnormalities occur in patients with severe alpha$_1$-antitrypsin deficiency, primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC). The impact of hepatic dysfunction on the respiratory system during sleep has recently been appreciated (Table 78-1).

Hepatopulmonary syndrome (HPS) and *portopulmonary hypertension* (POPH) are the major pulmonary vascular problems that complicate portal hypertension from any cause. HPS, a pulmonary vascular dilation abnormality leading to arterial hypoxemia, occurs in 5% to 15% of patients with portal hypertension. POPH, resulting from pulmonary vascular obstruction or obliteration, has been reported in 4% to 16.5% of patients with advanced liver disease. Pleural effusions related to the formation of ascites develop in 5% to 10% of cirrhotic patients.

Pulmonary function abnormalities can be demonstrated in approximately 50% of patients with advanced liver disease. The most common abnormality is a reduced diffusing capacity for carbon monoxide (DLCO). Abnormal oxygenation measured by increased alveolar-arterial oxygen gradient or reduced arterial oxygen tension (PaO_2) is common (40%-50%). Nocturnal oxygenation abnormalities are also common (~50%) and underdiagnosed in patients with advanced liver disease.

RISK FACTORS

Portal hypertension appears to be a prerequisite for the development of either HPS or POPH. Previous portosystemic surgical shunts have been reported in up to 30% of patients with POPH. Conditions leading to abnormal ascites usually precede the development of pleural effusions ("hepatic hydrothorax"). Smoking in the setting of ZZ or SZ α_1-antitrypsin deficiency genotypes leads to the greatest risk of emphysema and varying degrees of expiratory airflow obstruction. The Child-Pugh classification for the severity of liver diseases correlates poorly with most pulmonary consequences, with the exception of hepatic hydrothorax. The epidemic of hepatitis C disease does not appear to be related to any unique or common pulmonary abnormality, but the use of interferon-alpha to treat hepatitis C virus (HCV) infection is associated with well-documented drug-induced pulmonary side effects. The clinical presence of ascites or encephalopathy, as well as narcotic and sedative use, appears to predispose to abnormal overnight oximetry and sleep-disordered breathing.

PATHOPHYSIOLOGY

Circulating mediators, associated with the probable genetic predisposition, appear to cause HPS or POPH. Such mediators (causing vasodilation or vasoproliferation, respectively) could arise because of the abnormal metabolism of the dysfunctional liver. However, such specific circulating mediators have yet to be identified in humans.

Hepatopulmonary Syndrome HPS is characterized by arterial hypoxemia caused by precapillary-capillary dilations or direct arteriovenous communications. Excess perfusion for a given area of ventilation, diffusion limitation, and true anatomic shunting contribute to the degree of abnormal arterial oxygenation (Figure 78-1). Increased concentrations of exhaled nitric oxide have been demonstrated in HPS. Animal models of HPS have found upregulation of endothelin B receptors causing vasodilation and evidence of angiogenesis.

Portopulmonary Hypertension POPH results from vasoproliferation (endothelium and smooth muscle), along with in situ thrombosis, which causes an increased pulmonary vascular resistance (PVR) to arterial flow. It is important to note the various pulmonary hemodynamic patterns that may exist in the patient with advanced liver disease (Table 78-2).

Hepatic Hydrothorax Hepatic hydrothorax is a transudative pleural effusion caused by the formation of ascitic fluid. A combination of negative pleural pressure and positive abdominal pressure forces ascitic fluid into the pleural spaces through diaphragmatic defects and lymphatics. Rarely, the fluid may be chylous; infected pleural fluid may occur in the presence of spontaneous bacterial peritonitis.

Primary Biliary Cirrhosis and Primary Sclerosing Cholangitis PBC has systemic manifestations presumably because of autoimmune phenomena. Pulmonary granulomas, lymphocytic infiltrates, and organizing pneumonia can result. Rarely, both PBC and PSC may be associated with airway inflammation, hilar adenopathy, and mediastinal adenopathy (noncaseating granulomas found at biopsy).

Alpha$_1$-Antitrypsin Deficiency Severe deficiency of the circulating alpha-1 protein is caused by single point mutations in the synthesis of this protein within hepatocytes. Accumulation of polymerized protein within the endoplasmic reticulum of hepatocytes leads to clinically significant deficiency in serum

Table 78-1 Major Pulmonary Consequences of Portal Hypertension (with or Without Cirrhosis)

Area/Disorder	Complications
Pleural space	Hepatic hydrothorax Chylothorax Thoracobiliary fistulas Elevated hemidiaphragms caused by massive ascites
Pulmonary parenchyma	Bronchitis/bronchiectasis Emphysema (ZZ or SZ α_1-antitrypsin deficiency) Organizing pneumonia (PBC) Lymphocytic interstitial pneumonia (PBC) UIP or NSIP (PBC, autoimmune hepatitis/HCV therapy) Hilar/mediastinal lymphadenopathy (PBC, PSC)
Pulmonary circulation	Hepatopulmonary syndrome (HPS) *Pulmonary hypertension* High flow state Excess volume Left ventricular dysfunction Portopulmonary hypertension (POPH)
Sleep-disordered breathing	Frequent and severe nocturnal Sa_{O_2} changes Effects of massive ascites and encephalopathy Obstructive sleep apnea (OSA)

HCV, hepatitis C virus; *NSIP*, nonspecific interstitial pneumonia; *PBC*, primary biliary cirrhosis; *PSC*, primary sclerosing cholangitis; *Sa*$_{O_2}$, arterial oxygen saturation; *UIP*, usual interstitial pneumonia.

α_1-antitrypsin (especially in ZZ and SZ genotypes). Such deficiency subsequently leaves neutrophil elastase unopposed within the lung, causing lung damage (panacinar emphysema and bronchiectasis).

CLINICAL FEATURES

Exertional dyspnea is the most common, nonspecific presentation of any pulmonary consequence of liver dysfunction.

Hepatopulmonary Syndrome Finger clubbing, cyanosis of the digits, and spider angiomas suggest the arterial hypoxemia of HPS. The chest examination is usually unremarkable; no wheezing or inspiratory crackles are heard. Worsening dyspnea (platypnea) and arterial oxygenation (orthodeoxia) on moving from the supine to the standing position is frequently noted in the HPS patient.

Portopulmonary Hypertension Chest pain, pressure, and palpitations suggest advanced manifestations of POPH. Syncope is especially worrisome for severe POPH. An accentuated second heart sound (increased P_2) is common is POPH. The murmur of tricuspid regurgitation (systolic; over fourth intercostal space to left of sternum) may be heard.

Primary Biliary Cirrhosis and Primary Sclerosing Cholangitis Inspiratory crackles in the lower lung fields heard during auscultation may be associated with the interstitial lung problems that complicate PBC (lymphocytic alveolitis) or chronic aspiration in patients with hepatic encephalopathy. Productive sputum may be related to the airway abnormalities (bronchiectasis) associated with α_1-antitrypsin deficiency or PSC (bronchitis).

Hepatic Hydrothorax Pleural effusion caused by liver dysfunction will be associated with diminished breath sounds depending on the location and extent of the pleural effusion. Egophony (verbalized "e" sounds like "a" to listener) suggests atelectatic lung caused by compressive pleural effusions; affected patients may have significant hypoxemia. Pleural rubs are rare; pleuritic or chest wall pain is not a symptom of hepatic hydrothorax and suggests another diagnosis, such as an autoimmune disorder or pulmonary embolism.

Alpha$_1$-Antitrypsin Deficiency Signs and symptoms are similar to advanced chronic obstructive lung disease (COPD), especially emphysema (hyperinflation of chest; prolonged expiratory phase with/without wheezing). Chest radiography and computed tomography (CT), however, suggest predominantly lower lung field distribution of emphysematous or bullous abnormality. Such changes are seen only in the severely deficient ZZ or SZ genotypes; MZ genotypes have minimal, if any, lung damage. Approximately 50% of cirrhotic patients with ZZ or SZ phenotypes have abnormal pulmonary function tests (PFTs), such as increased residual volume and reduced forced expiratory volume in 1 second (FEV_1).

Sleep-Disordered Breathing Excess fatigue and daytime hypersomnolence caused by sleep-disordered breathing may be confused with effects of liver disease and anemia. Sleep-related oxygenation abnormalities and effects on liver metabolism, such as insulin resistance resulting from hypoxic liver injury, have been documented. Furthermore, improvement in liver enzyme levels after treatment of obstructive sleep apnea (OSA) with continuous positive airway pressure (CPAP) also supports the diagnosis of hypoxic injury that occurs overnight. Chronic fatigue after liver transplant (LT) has been a major problem regardless of posttransplant duration, greatly impacting the patient's daily functioning and quality of life. A significant relationship was found between severity of post-LT fatigue and sleep quality, as assessed by the Pittsburgh Sleep Quality Index (PSQI).

DIAGNOSIS

Hepatopulmonary Syndrome The HPS diagnosis is established by demonstrating pulmonary vascular dilation as the cause for hypoxemia. Hypoxemia is usually defined as Pa_{O_2} less than 80 mm Hg or alveolar-arterial oxygen gradient greater than 15 to 20 mm Hg. Two noninvasive methods are available to document abnormal pulmonary vascular dilation. Qualitatively, a positive contrast-enhanced transthoracic echocardiogram reflects the passage of microbubbles (usually absorbed during a first pass through normal lungs) through dilated pulmonary vessels, with subsequent detection in the left atrium. Quantitatively, an abnormal brain uptake of technetium-labeled macroaggregated albumin (^{99m}Tc MAA) (uptake > 6%) after lung perfusion reflects the passage of radiolabeled albumin aggregates through the lungs and subsequent uptake in the brain (Figure 78-2). Contrast echocardiography is more sensitive than ^{99m}Tc lung scanning to detect pulmonary vascular dilation. A lung biopsy is not necessary. Figure 78-3 provides a practical clinical algorithm for the evaluation of suspected HPS.

Portopulmonary Hypertension Screening for pulmonary hypertension is accomplished by transthoracic Doppler echocardiography. Increased right ventricular systolic pressure (RVSP) greater than 50 mm Hg suggests but does not prove clinically

Figure 78-1 Mechanisms of arterial hypoxemia in hepatopulmonary syndrome. **A,** Normal ventilation and evenly matched perfusion; no anatomic shunts. **B,** Many capillaries are dilated with blood flow that is not uniform, and ventilation-perfusion excess mismatch occurs. Restricted oxygen diffusion into the center of the dilated capillaries occurs. Anatomic shunts that bypass the alveoli can develop. Hypoxemia evolves from each of these abnormalities. *(From Rodriguez-Roisin R, Krowka MJ:* N Engl J Med *358:2378–2387, 2008.)*

Table 78-2 Pulmonary Hemodynamic Patterns Associated with Advanced Liver Disease

Pattern	MPAP	CO	PAOP	TPG	PVR
High-flow, hyperdynamic circulatory state*	↑	↑↑	↓	↓	↓
Excess volume[†]	↑	↑	↑	↑↓	↑↓
Portopulmonary hypertension					
Normal volume[‡]	↑↑↑	↑→↓	↓	↑↑↑	↑↑↑
Excess volume	↑↑↑	↑→↓	↑	↑↑	↑↑

Specific data associated with these patterns in Okcay A et al: *Hepatology* 44:455, 2009.

CO, cardiac output (normal usually 4-5 L/min); *MPAP,* mean pulmonary artery pressure (normal <25 mm Hg); *PAOP,* pulmonary artery occlusion pressure (same as pulmonary capillary wedge pressure, PCWP); *PVR,* pulmonary vascular resistance (TPG/CO; normal <3 Wood units, or 240 dynes.sec.cm^{-5}); *TPG,* transpulmonary gradient (MPAP – PAOP; normal <12 mm Hg).

*This pattern usually seen in HPS.

[†] Depending on the duration and reason for excess volume, PVR and TPG may be increased or normal.

[‡] As POPH worsens, PVR increases, right side of heart fails, and CO declines.

significant POPH. A right-sided heart catheterization must be accomplished to establish the diagnosis. Figure 78-4 provides a screening algorithm used at the Mayo Clinic; clinicians may have other criteria to determine candidates for right-sided heart catheterization. Most centers adhere to the triad of mean pulmonary artery pressure (MPAP) greater than 25 mm Hg, normal pulmonary capillary wedge pressure (PCWP) less than 15 mm Hg, and increased pulmonary vascular resistance (PVR) greater than 240 dynes.sec.cm^{-5}) as definitive criteria for POPH. A lung biopsy is neither necessary nor advised. Chronic pulmonary emboli should be excluded.

Hepatic Hydrothorax This is a clinical diagnosis based on the chest radiograph showing a pleural effusion that can be right-sided (70%), left-sided (15%), or bilateral (15%). Thoracentesis is usually performed only when dyspnea is extreme, or atypical symptoms (e.g., pain, fever) exist suggesting another process such as empyema or metastatic hepatocellular carcinoma. Hepatic hydrothorax may occur in the absence of clinical ascites.

Alpha$_1$-Antitrypsin Deficiency Pulmonary dysfunction in the setting of severe α_1-antitrypsin deficiency should be established by standard PFTs, to assess degree of expiratory airflow limitation and hyperinflation, and high-resolution CT (HRCT) of the chest, to assess for subclinical emphysema, bullae, and bronchiectasis. A combination of abnormal serum genotypes (usually ZZ or SZ, with MM normal) and decreased α_1-antitrypsin level confirms the diagnosis.

Sleep-Disordered Breathing Overnight oximetry (OvOx) using finger pulse monitoring to screen for abnormal nocturnal oxygenation is inexpensive and clinically important. Abnormal OvOx abnormalities include frequent and severe hemoglobin desaturation (Figure 78-5). These abnormalities are common

in LT candidates despite a lack of daytime somnolence. Abnormal OvOx is associated with massive ascites, encephalopathy, and increased baseline alveolar-arterial oxygen gradients. If OvOx is abnormal, formal *polysomnography* (PSG; overnight sleep study with multiple variable noninvasive monitoring) should be conducted. PSG is the "gold standard" to diagnose specific sleep-disordered breathing etiologies.

TREATMENT

Hepatopulmonary Syndrome No pharmacologic treatments have proved efficacious in improving arterial hypoxemia caused by HPS. Liver transplantation (LT) is the treatment of choice. Rarely, coil embolization of discrete arteriovenous communications that occur in HPS can improve oxygenation. Supplemental oxygen should be given depending on PaO_2 levels at rest, with exertion, and during sleep.

Portopulmonary Hypertension Significant improvement in pulmonary hemodynamics has been reported with the long-term use of continuous 24-hour intravenous (IV) infusion of the prostacyclins *epoprostenol* and *treprostinil*, as well as with the oral endothelin receptor antagonists *ambrisentan* and *bosentan* and the phosphodiesterase inhibitor *sildenafil*. LT is a high-risk procedure in the patient with POPH and is contraindicated if pulmonary vasomodulating therapy does not result in MPAP less than 50 mm Hg and satisfactory right-sided heart function.

Minimal variations in SaO_2 and no drops in SaO_2 below 90% saturation. **B,** Desaturator: defined as SaO_2 less than 90% more than 10% of sleep time; and frequent drops in SaO_2 greater than 4%.

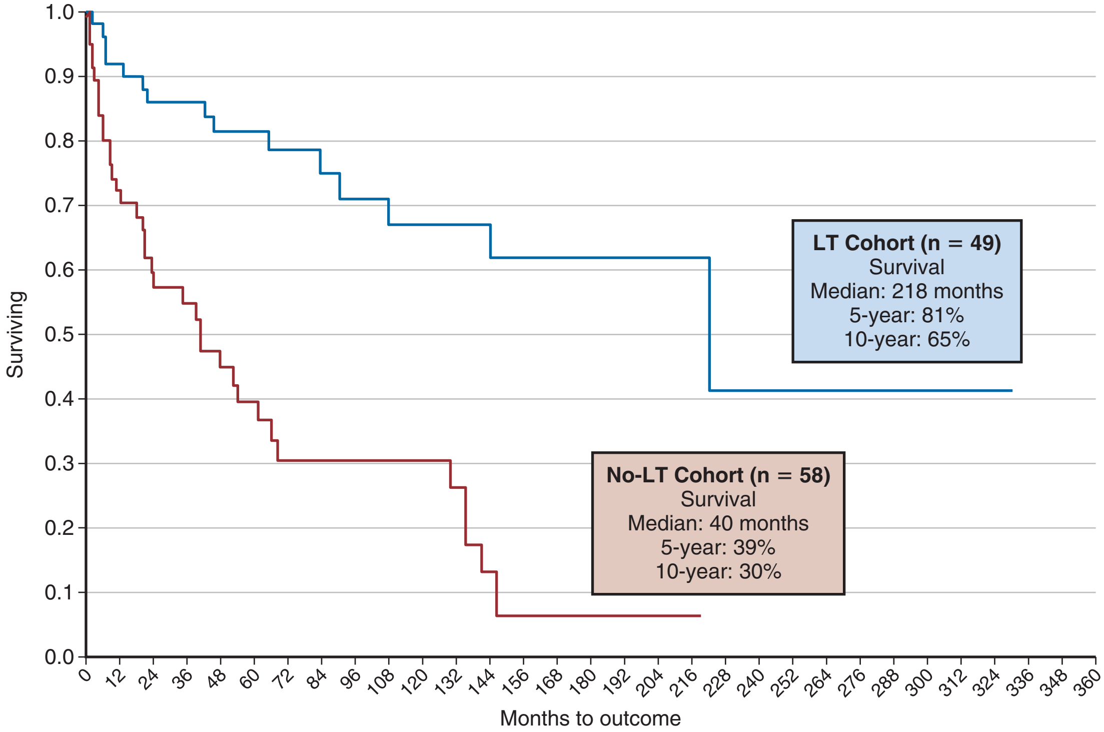

Figure 78-6 Long-term outcome (5-year and 10-year survival) in patients with hepatopulmonary syndrome, lung transplant *(LT)* cohort versus no lung transplant *(no-LT)* cohort. *(From Iyer V et al:* Liver Transpl *17:S130, 2011).*

Hepatic Hydrothorax Salt restriction and aggressive diuresis, as tolerated by renal function, with furosemide and spironolactone are treatment cornerstones. Repetitive thoracentesis is not advised. Chest tube drainage with pleurodesis and video-assisted thoracoscopy rarely provide long-term improvement, by obliterating the pleural space and repairing diaphragmatic defects, respectively. *Transjugular intrahepatic portosystemic shunting* (TIPS) is appropriate treatment for refractory hepatic hydrothorax, as is LT. Outcome of LT is not affected by the presence of hepatic hydrothorax.

Severe α_1-Antitrypsin Deficiency and Abnormal Pulmonary Function In the patient with clinically significant liver disease and severe serum α_1-antitrypsin deficiency (<80 mg/dL), augmentation therapy to replace the protein by weekly or biweekly infusions is appropriate, safe, and may prevent further lung damage. There is no role for treating α_1-antitrypsin liver disease (cirrhosis) with replacement therapy. LT results in the phenotype of the donor liver, normalizes the serum α_1-antitrypsin level, and presumably prevents further lung damage. LT in the patient with serious liver dysfunction caused by ZZ or SZ phenotype may be problematic and must be considered on a case-by-case basis.

Sleep-Disordered Breathing Treatments range from simple supplemental oxygen during sleep by nasal cannula to the use of masks to deliver CPAP or biphasic positive airway pressure (BiPAP). Treating ascites (diuresis) and encephalopathy (oral osmotic laxatives) may be helpful. The effect of LT on sleep-disordered breathing has yet to be studied.

CLINICAL COURSE

Hepatopulmonary Syndrome Few data exist to characterize the clinical course in HPS. In the largest series to date, 5-year survival associated with LT was 76% versus 23% in non-LT group (Figure 78-6). Complete resolution of HPS often follows LT; the time to resolution is directly related to the severity of hypoxemia and may take months. Mortality is rarely a direct consequence of hypoxemia.

Portopulmonary Hypertension The 5-year survival without pulmonary vasodilator treatment is 4% to 14%. Mortality is equally the result of progressive right-sided heart failure and the complications related to liver disease. Long-term survival benefit has been noted with 24-hour continuous IV epoprostenol therapy in POPH versus no treatment. Despite pulmonary vasomodulating therapy, successful outcome during and after LT remains problematic and unpredictable. Despite aggressive therapy, POPH may resolve, remain stable, or progress following LT.

Alpha$_1$-Antitrypsin Deficiency In patients with the ZZ phenotype, long-term survival is significantly reduced in smokers. No data describe the long-term outcomes in patients with ZZ phenotype, cirrhosis, and pulmonary function abnormalities, with or without LT. The risk of liver cancer increases with age in ZZ patients.

Sleep-Disordered Breathing The effect of arterial hypoxemia (nocturnal or daytime) on hepatic function that may already be impaired is poorly understood. Better nocturnal oxygenation using supplemental oxygen or airway devices may significantly improve quality of life, as well as ameliorate cardiovascular dysfunction (rhythm disturbances, systemic hypertension).

PITFALLS AND CONTROVERSIES

Transjugular intrahepatic portosystemic shunting may or may not have a therapeutic role in the treatment of HPS. TIPS may acutely worsen pulmonary hemodynamics because of increased preload and therefore may be contraindicated in the POPH patient.

The priority for lung transplant in patients with either HPS or POPH is evolving; PaO_2 less than 60 mm Hg from HPS now warrant higher priority for LT. In POPH it is hypothesized that pulmonary hemodynamic improvement with pulmonary vasodilators (goal of MPAP <35 mm Hg and PVR <400 dynes.sec.cm^{-5}, or normalization of PVR with good right ventricular function) may facilitate safe LT and improved long-term survival. The optimal medical therapy (prostacyclins, endothelin receptor antagonists, or phosphodiesterase inhibitors) for POPH has yet to be defined.

The role of hepatitis C infection causing pulmonary dysfunction is debatable. Interferon therapy (standard or pegylated forms) may cause a sarcoidlike reaction within the lungs. Organizing pneumonia has also been reported with such therapy, and discontinuance of therapy and corticosteroids usually resolve the pulmonary process.

Symptoms of fatigue in the patient with advanced liver disease may be caused by treatable sleep-disordered breathing and abnormal nocturnal oxygenation. Therefore, screening overnight oximetry should be a routine diagnostic consideration in such patients.

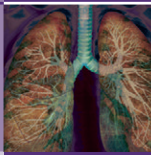
SPECIAL CLINICAL CONDITIONS



Chapter 79

Inflammatory Bowel Disease

Frank Schneider • Kristen L. Veraldi

Thoracic involvement by Crohn disease (CD) and ulcerative colitis (UC) is part of the spectrum of extraintestinal manifestations of inflammatory bowel disease (IBD). The distinctive pathologic changes associated with IBD can involve the upper respiratory tract, the large and small airways, the interstitium of the lung, the pleura, and the heart and pericardium. It is often difficult to prove with certainty that a particular lung disease is causally related to an IBD. The presentation is not always temporally related to the bowel disease, and the pathologic findings can overlap with those seen in other inflammatory lung diseases. However, the correlation of pulmonary function with IBD severity and the striking response to corticosteroid therapy by many of the lesions suggests a common mechanism.

Anatomically, the gastrointestinal and respiratory systems have some common features. The cephalad end of the respiratory tract (larynx and trachea) is intimately associated with the foregut until their separation by the mesodermal tracheoesophageal folds. Both epithelia are of endodermal origin, and both mucosal surfaces contain mucosa-associated lymphoid tissue (MALT), columnar epithelium with surface differentiations (villi and cilia), goblet cells, and submucosal glands. The pathogenesis of extraintestinal manifestations is poorly understood. The emerging theme of the proposed mechanisms for bowel damage in IBD is an intricate interplay among innate and acquired immunologic factors, intraluminal microbial flora, and the mucosal barrier separating both. Several studies found a limited repertoire of T cell specificity in IBD patients, suggesting that a cellular immune response is elicited by only a small number of antigens. Autoantibodies, including atypical antinuclear antibodies (ANAs), found in some patients suggest an aberrant B cell functionality. The diapedesis (migration) of inflammatory cells into areas of inflammation suggests abnormalities in the homing of leukocytes. Lastly, increased levels of cytokines (e.g., interferon, tumor necrosis factor) suggest a dysregulation of inflammatory mediators in patients with IBD. Evidence has been found supporting all these mechanisms in sites other than the respiratory tract.

In addition, genetic linkage studies of affected kindred have identified several genes associated with IBD. The first susceptibility gene discovered (IBD1, also known as NOD2) encodes a protein that activates transcription in macrophages on encountering bacterial lipopolysaccharides. Another, more recent, example is the discovery of nonfunctional variants of the interleukin-23 (IL-23) receptor or some of its downstream effectors. IL-23 helps generate Th17 helper cells that play a central role in immune response regulation. Genetic factors are associated not only with the development of IBD but also with its extraintestinal manifestations. A study of more than 250 parent-child and sibling pairs showed concordance of extraintestinal involvement in 70% and over 80% of the pairs, respectively. Other studies more specifically sought associations with certain genes. IBD1 and IL-23 are associated with sacroiliitis and ankylosing spondylitis, respectively. CD patients carrying major histocompatibility complex (MHC) genes *HLA-A2*, *HLA-DR1*, *HLA-DQw5*, *HLA-DRB1*0103* (DR103), or *HLA-B*27* are more likely to develop extraintestinal manifestations. UC patients with *HLA-B*58* have been found to have more joint, skin, and eye manifestations. *HLA-B8* is more common in UC patients with primary sclerosing cholangitis than those without. No specific genetic link has been established between IBD and respiratory tract involvement. However, some genetic alterations may also be involved in other lung diseases; abnormalities of NOD2, for example, have been found in early-onset and advanced pulmonary sarcoidosis.

Thoracic conditions seen in IBD can conceptually be grouped into four categories: (1) nonspecific conditions (e.g., infection), (2) anatomic complications (e.g., fistulas); (3) therapy-related complications (e.g., drug toxicity); and (4) distinctive pathologic changes that statistically show a more-than-incidental association with IBD. This chapter focuses on the fourth category.

EPIDEMIOLOGY

The true incidence of thoracic complications in IBD patients is unknown. There have been no screening tests performed on large populations of IBD patients. The proportion of IBD patients with subjective respiratory symptoms such as cough, sputum production, wheezing, or shortness of breath has been reported to be as high as 50%. One or more pulmonary function tests (PFTs) are abnormal in approximately 40% of IBD patients, with forced expiratory volume in 1 second (FEV_1), inspiratory vital capacity (IVC), or diffusion capacity (DLCO) showing a 10% to 30% reduction. Between 25% and 50% of asymptomatic IBD patients show abnormalities on high-resolution computed tomography (HRCT) scans. Often, the findings are subtle and include ground-glass opacities, mosaicism suggestive of air trapping, peripheral opacities, and cysts. At the other end of the spectrum are case reports and small series of patients with distinctive manifestations of thoracic involvement. These reports, accounting for 155 patients, were recently reviewed (see Suggested Readings). Although nothing is offered to calculate incidence or prevalence, significant symptomatic thoracic involvement by IBD probably is not a common event. However, it is common enough that physicians need to be cognizant of IBD to recognize it and prevent the potentially debilitating consequences of some of its forms.

The temporal relation of the thoracic manifestation to the bowel disease varies. Approximately 80% of patients have an established history of IBD, whereas in about 10% each, the thoracic symptoms precede the bowel disease or develop concomitantly. About one half of patients with airway disease have had a colectomy, and occasionally the onset of airway disease follows the colectomy by days or weeks, suggesting a shift of the inflammatory reaction from the gut to the bronchial tree.

In ulcerative colitis and Crohn disease, the most common anatomic structures involved are the large airways (39%), followed by infiltrative lung disease (23%) and involvement of the serosa (13%). Small airways inflammation (10%), upper airways inflammation (9%), and involvement of the pulmonary vasculature (6%) are slightly less common. In general, respiratory tract involvement is more common in UC than CD patients. In both diseases, however, all compartments of the respiratory tract can be affected, although with slight differences in incidence.

Severity of thoracic involvement in many cases parallels disease activity in the bowel. Patients with active IBD have a greater chance of exhibiting airway obstruction. Inflammation of the bowel also correlates inversely with diffusion capacity. Serosal disease is more common among those with active IBD, while parenchymal disease is often seen in patients with quiescent bowel disease.

Women appear to be more frequently affected (~2 : 1). When considering only airway disease, this ratio increases up to 4 : 1. However, pleural involvement is about equally distributed between women and men.

Two thirds of patients with thoracic complications also have other extraintestinal manifestations at the same time, such as involvement of the skin, eyes, joints, or the biliary tract. Smoking does not appear to be a risk factor for developing airway inflammation in IBD, because most patients with this manifestation are nonsmokers.

Interestingly, two recent analyses found that CD patients appear to have a slightly increased risk of lung cancer, whereas the risk appears to be decreased in UC patients (standardized incidence ratios of 1.82 vs. 0.39 and 0.72, respectively).

CLINICAL AND PATHOLOGIC FEATURES

The diagnostic workup should include chest radiograph and CT scan. PFTs should be obtained, if possible, because they can provide a baseline in the course of treatment. Endoscopy complements imaging studies in the detection of upper airway obstruction or stenosis and in obtaining material for microbiology and histologic studies. A complete blood count with differential as well as a metabolic panel should be performed. Erythrocyte sedimentation rate and C-reactive protein may be helpful in following disease activity during treatment. Between 50% and 70% of patients with ulcerative colitis and 10% to 30% of patients with Crohn disease (predominantly those with colonic involvement) show atypical antineutrophil cytoplasmic antibodies (ANCAs), characterized by a fine granular and perinuclear ("snowdrift") pattern. Serologic testing for ANCAs may be helpful in patients with suspected underlying IBD. ANAs can help identify drug-induced lupus syndrome in patients with serositis. Since thromboembolic disease is a known cause of morbidity and mortality in IBD patients, the physician should maintain a low threshold to consider and exclude pulmonary embolism in this population.

This section discusses the different compartments of the respiratory tract involved by IBD, including unique considerations of the particular location, clinical presentation, and its pathologic features (**Table 79-1**).

AIRWAY DISEASE

Inflammatory bowel disease can affect the entire tracheobronchial tree, including larynx, trachea, and large and small airways, in the form of airway inflammation. Most common is inflammation of the large airways, seen in about 40% of IBD patients. Approximately 10% of patients show involvement of the upper respiratory tract or small airways. Extent and location of involvement are unpredictable; some patients have involvement restricted to a small area, some have patchy disease involving different anatomic levels of the conducting airways, and others show involvement of the entire tracheobronchial tree. The vast majority of patients with airway disease have UC, and only 10% CD. About two thirds of patients are female, with a median age at presentation of 42 years. In about 5% of patients the airway disease predates the diagnosis of IBD, and these patients tend to be much younger (median age, 13 years).

Clinically, laryngeal inflammation affecting the glottis and epiglottis produces narrowing and stenosis. Corresponding symptoms include dry, deep-toned cough with stridor. Severe cases may result in asphyxia, which is why laryngeal inflammation in IBD is one of the three conditions that require emergency treatment. Large airways inflammation in the form of tracheobronchitis manifests with chronic, otherwise unexplained cough that can be dry or productive of copious amounts of mucopurulent sputum. It is this purulent material that led to the historical designation for this condition, "chronic bronchial suppuration." It is also the condition that established the link between IBD and lung disease in 1976. Long-standing chronic inflammation and suppuration lead to bronchiectasis, often with basilar distribution. Small airways disease manifests as airflow obstruction with or without sputum production. Although unlikely to be the dominant feature, microscopic involvement is often found distally from affected large airways.

Radiographically, airway walls appear thickened with a "tram line" pattern. Larger airways show mucus plugging, smaller airways a tree-in-bud appearance. These changes tend to occur in a basilar-predominant distribution, occasionally with associated volume loss. Small airways disease can be associated with a tree-in-bud pattern, diffuse reticular shadows, or mosaic pattern due to air trapping (**Figure 79-1**). Bronchiectasis after long-standing disease can range from prominent thick-walled bronchi to subtle increases in airway caliber (**Figure 79-2**).

Bronchoscopically, the large airways show variable, but often severe, inflammation. Scarred bronchial granulomas are sometimes seen in patients with CD.

Histologically, large airways inflammation in IBD is characterized by a mucosal mononuclear inflammatory infiltrate, which is often bandlike and resembles that seen in the bowel mucosa in IBD (**Figure 79-3**, *A*). A luminal exudate containing neutrophils is common (Figure 79-3, *B*). Granulomas are frequently but not always seen in lung biopsies from patients with CD. On the other hand, the presence of a granuloma in a biopsy does not exclude UC as the underlying bowel disease. Small airways inflammation is similarly suppurative, with chronic inflammation of the bronchiolar wall. Occasionally, interstitial foamy macrophages are present in a centrilobular distribution, morphologically resembling diffuse panbronchiolitis. Late-stage small airways involvement may histologically present as constrictive bronchiolitis, which can be patchy throughout the lung and therefore may be missed by the biopsy sampling. An

Table 79-1 Thoracic Involvement in Inflammatory Bowel Disease (IBD)

Pattern of Involvement[a]	UC*	CD*	Symptoms	Imaging	Bronchoscopy/ Pathology[b]	BAL	Treatment	Prognosis/ Outcome
Airway Disease								
Larynx, glottis, epiglottis: Inflammation and narrowing	++	+	Barking cough, noisy breathing, hoarseness, stridor, asphyxia	CT: Normal or narrowing	Glottic/subglottic inflammation (granulomatous in CD), inward bulging, marked stenosis; can show erosion or ulceration	ND	IV CS Laser ablation Emergent tracheostomy	Favorable
Trachea: Inflammation and narrowing	++	+	Dry/productive cough, dyspnea, chronic sputum, hemoptysis	CT: Normal or narrowing	Tracheal inflammation, edema, hemorrhage with consequent stenosis; can be impressive; possible granulomas in CD	ND	IV/oral CS Occasional response to infliximab therapy in CD	Variable
Main bronchi: Simple chronic bronchitis	++	±	Chronic cough, slightly productive, wheeze	Normal	Mild/moderate inflammation and redness of large airways Little or no stenosis	PMN	Inhaled CS with or without short burst of oral CS	Often spectacular effect with CS
Main bronchi: Chronic bronchial suppuration	++	+	Marked chronic cough, wheeze, copious sputum	Thickened bronchial walls "Dirty lungs"	Large airway inflammation, often severe Deep-seated inflammatory cell infiltrate	PMN	Inhaled or oral CS *or* nebulized CS Early treatment recommended	Variable Residual symptoms and physiologic impairment common
Main bronchi: Bronchial distention[c]	+	–	Asymptomatic or cough	CT: Airway distention	ND	ND	CS if patient symptomatic	May recover with CS
Main bronchi: Mucoid impaction	+	–	Asymptomatic	CT: Branched shadows	ND	ND	Watching or CS	Good
Main bronchi: Disseminated endo-bronchial granulomas	–	+	Chronic cough	CT: Normal or narrowing	Spotted granulomas	ND	Oral CS with or without inhaled CS	Unknown
Main bronchi: Bilateral bronchiectasis	++	+	Chronic cough and wheeze Often, abundant sputum Hemoptysis	Thickened and dilated bronchi Mucoid impaction Tree-in-bud pattern distally	Widespread airway inflammation and narrowing Exuberant cellular infiltrate Luminal exudate, metaplastic epithelium	PMN	Inhaled or oral CS Nebulized CS Serial bronchial lavages with CS Rarely resection of affected lobe indicated	Variable residual impairment despite CS treatment is common Refractoriness to all forms of CS unusual
Small airways[d]: Acute purulent bronchiolitis[a]	+	+	Nonproductive cough with or without dyspnea	Small irregular opacities Mosaic on CT	ND	ND	Oral CS (possibly with added inhaled CS)	Variable
Small airways[d]: Granulomatous bronchiolitis[a]	-	+	Nonproductive cough with or without dyspnea	Small irregular opacities Mosaic on CT	ND	Ly	Oral CS	Favorable
Small airways[d]: Diffuse panbronchiolitis pattern	+	–	Dyspnea with or without sputum production	Tree-in-bud pattern Mosaic on CT	Normal/mild inflammation	ND	Oral CS (possibly with added inhaled CS)	May progress to COPD
Small airways[d]: Constrictive bronchiolitis	+	–	Dyspnea	ND	Normal	ND	Inhaled or oral CS	Associated with moderate-to-severe COPD

Continued

Table 79-1 Thoracic Involvement in Inflammatory Bowel Disease (IBD)—cont'd

Pattern of Involvement[a]	UC*	CD*	Symptoms	Imaging	Bronchoscopy/ Pathology[b]	BAL	Treatment	Prognosis/ Outcome
Air Space and Interstitial Disease								
Organizing pneumonia (OP)	+	+	Dry cough, dyspnea, fever, ARF	Bilateral focal or diffuse infiltrates	N	Var	Oral or IV CS, depending on severity	Mostly favorable; this pattern may also be caused by drugs
Eosinophilic pneumonia (EP)[†]	+	±	Dry cough, malaise, dyspnea (and at night); slight fever	Bilateral focal or diffuse infiltrates	N	Eos	Oral or IV CS, depending on severity	Mostly favorable; this pattern may also be caused by drugs
Nonspecific interstitial pneumonia	+	+	Dry cough, dyspnea	Basilar or diffuse opacities	N	Ly	Oral or IV CS, depending on severity	Mostly favorable; this pattern may also be caused by drugs
Infiltrative lung disease, granulomatous	±	++	Dry cough, dyspnea	Diffuse shadowing	N	Ly	Oral or IV CS, depending on severity	Favorable
Infiltrative lung disease, desquamative	+	–	Dyspnea	Disseminated pulmonary opacities	N	ND	Oral or IV CS, depending on severity	Favorable
Sterile necrobiotic nodules	+	–	Dyspnea, sometimes dull chest pain Can occur with cutaneous pyoderma gangrenosum	Multiple lung nodules, sometimes with cavitation	N	ND	Oral or IV CS, depending on severity	Favorable
Pleural Disease								
Pleural effusion	+	+	Chest discomfort, pleuritic chest pain	Pleural effusion	–	–	Drainage NSAIDs CS	Favorable
Pneumothorax			Stabbing chest pain, dyspnea	Medial pneumothorax to be differentiated from pneumomediastinum	–	–	Exsufflation	Favorable
Pericardial and Cardiac Disease								
Pericarditis Pericardial effusion Myocarditis	+	+	Anterior chest pain, tamponade, arrhythmias, heart block, heart failure	Enlarged heart	–	–	Drainage NSAIDs CS	Favorable; pericardial constriction unusual

*CD, Crohn disease; UC, ulcerative colitis; ++, quite common, suggestive; +, occasional; ±, uncommon; –, not described, does not apply.

[†] In this context, eosinophilic pneumonia is also often referred to as "pulmonary infiltrates with eosinophilia" (PIE).

[a] Location of airway inflammation tends to remain the same with time in a given patient (e.g., in upper airway, trachea, bronchi, or small airway) but may vary depending on the patient and in some cases, time into the disease.

[b] Not all cases reach pathology.

[c] Very few cases/data available for review, or unpublished.

[d] In some patients, pneumothorax or pneumomediastinum occur in association.

Modified from Camus P, Colby TV: *Eur Respir J* 15:5–10, 2000.

ARF, acute respiratory failure; *BAL*, bronchoalveolar lavage; *COPD*, chronic obstructive pulmonary disease; *CS*, corticosteroids or corticosteroid treatment; *CT*, computed tomography; *Eos*, eosinophils; *IV*, intravenous; *Ly*, lymphocytes; *N*, normal; *ND*, no data available; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PMN*, polymorphonuclear neutrophil leukocytes; *Var*, variable.

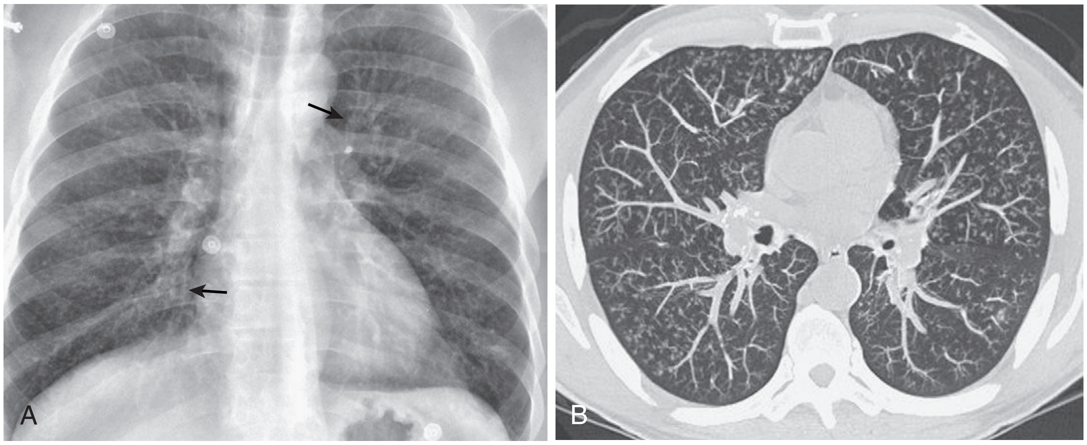


Figure 79-1 Involvement of large and small airways in ulcerative colitis. **A,** Plain chest radiograph of chronic bronchiolitis shows overall increase in nonspecific lung markings (“dirty lung”) and occasional “tram tracks” related to bronchial wall thickening *(arrows).* **B,** Chest CT scan of cellular bronchiolitis with tree-in-bud pattern. *(Courtesy Dr. Carl Fuhrman, University of Pittsburgh Medical Center.)*

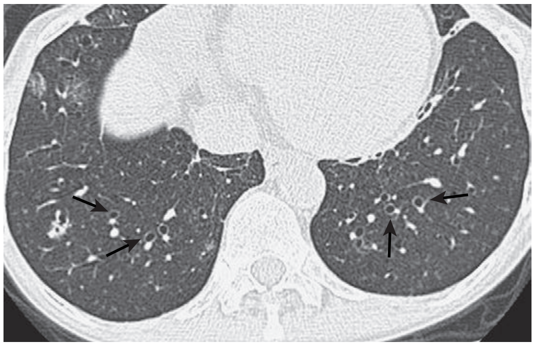

Figure 79-2 Bronchiectasis in patient with inflammatory bowel disease as a result of long-standing chronic bronchitis. The chest CT scan shows increased airway caliber *(arrows)* compared with adjacent pulmonary arteries. *(Courtesy Dr. Carl Fuhrman, University of Pittsburgh Medical Center.)*

expiratory chest CT scan showing air trapping may support a clinical impression of obliterative small airways disease in these patients.

AIR SPACE DISEASE

Inflammatory bowel disease can involve the distal air spaces of the lung in the form of *organizing pneumonia* (OP) or *eosinophilic pneumonia* (EP). The main difficulty with these patterns of involvement is distinguishing them from infection and drug-related lung disease. Clinically, patients present with shortness of breath ranging from moderate dyspnea to acute respiratory failure, sometimes accompanied by fever. Radiographically, OP shows bilateral, ovoid, elongated subpleural opacities, which may contain air bronchograms (**Figure 79-4**, *A* and *B*). EP, similar to non-IBD cases, may assume a masslike appearance or manifest as migratory opacities. Bronchoalveolar lavage (BAL) findings are often nonspecific, but an increase in neutrophils or eosinophils suggests a diagnosis of infection or EP, respectively.

Histologically, OP is characterized by loose, fibroblastic plugs in air spaces (Figure 79-4, C), whereas EP shows numerous eosinophils within the interstitium and among fibrinous air space exudates. Both patterns are nonspecific and can also be seen in infections, drug reactions, connective tissue disease, airway obstruction, or cryptogenic (idiopathic) forms of OP and EP. Biopsies may still be helpful to rule out infection or other causes of air space disease.

INTERSTITIAL LUNG DISEASE

Diffuse interstitial lung diseases described in IBD patients include nonspecific interstitial pneumonia (NSIP) and granulomatous interstitial pneumonia, the latter almost exclusively seen in CD. Rare cases with usual interstitial pneumonia (UIP) or desquamative interstitial pneumonia (DIP) patterns have been reported. In some patients, IBD-related interstitial lung disease has been found to coexist with sarcoidosis. The reason for this association is unknown, but the presence of granulomas and similar T cell subpopulations in both diseases may indicate a pathogenetic connection.

Patients with interstitial lung disease present with shortness of breath and crackles on auscultation. Radiographically, interstitial markings are increased, and often more prominent in the lower lung zones (**Figure 79-5**, *A*). Bronchoscopic examination is normal unless concomitant airway disease is present. Wedge biopsies are necessary for histologic confirmation of diffuse fibrosing lung disease, because transbronchial biopsies are usually too small for assessing the fibrosis pattern. Biopsies show interstitial collagen fibrosis with variable mononuclear inflammatory infiltrates with or without granulomas (Figure 79-5, *B* and C). The presence of granulomas should always prompt exclusion of infection with special histochemical stains or preferably by concomitantly submitted tissue culture.

MASSES AND NODULES

Necrobiotic nodules are an uncommon manifestation in ulcerative colitis and Crohn disease. Nodules may occur synchronously with pyoderma gangrenosum lesions in the skin, with common histologic features. One study found that necrobiotic nodules precede the diagnosis of IBD in one third of patients. Patients present with a rapid onset of fever, dyspnea, and chest pain. Imaging studies show multiple rounded lung nodules that may cavitate over time (**Figure 79-6**, *A*). Without intervention, nodules may eventually disappear, leaving a scar. The histologic picture is distinctive, showing aggregates of neutrophils and necrosis without granulomatous features or identifiable infectious organisms (Figure 79-6, *B*). Although drug-induced lung injury can present with lung nodules, these nodules tend

not to show cavitation radiographically or sterile abscesses histologically.

SEROSAL DISEASE

Serosal membranes may be involved in the form of pleural or pericardial inflammation and thickening or effusions. Patients complain of pleuritic or anterior, sometimes position-dependent, chest pain and sometimes fever. Radiographs or echocardiography may be able to demonstrate an effusion, which if sampled is characteristically exudative and rich in neutrophils. Complications to consider are the possibility of tamponade and associated myocarditis. Electrocardiographic (ECG) changes such as arrhythmias or conduction blocks may indicate myocarditis. Serositis or effusions associated with drug-induced lupus can be identified by the presence of ANAs.

MEDIASTINAL DISEASE

Pneumomediastinum of uncertain pathogenesis has been described in a few UC patients. Because it seems to correlate with disease flares, it could be a result of acute airway obstruction, analogous to the pneumomediastinum seen in asthma attacks. Another possibility is the development of small fistula tracts between colon and mediastinum.

RARE MANIFESTATIONS

Some conditions have only been described in reports of a single or few cases, and the strength of association with IBD is uncertain. These include *eosinophilic pneumonia* (to be distinguished from drug effect), *Langerhans cell histiocytosis* (to be distinguished from reactivation by therapy), and *Wegener granulomatosis* (to be distinguished from primary Wegener granulomatosis which can present with colitis).

DRUG-INDUCED LUNG DISEASE

A major difficulty when encountering patients with apparent lung involvement by IBD is excluding drug-related toxicity. A causal role of drugs in airway inflammation is unlikely for two reasons. First, airway inflammation is common among IBD patients after colectomy and no longer receiving culprit drugs such as sulfasalazine or mesalamine. Second, airway inflammation does not improve on withdrawal of these drugs in patients with no history of colectomy. Infiltrative (air space or interstitial) lung disease, on the other hand, is a pattern associated with several drugs used in IBD patients. Unfortunately, withdrawal of the drug does not always result in stabilization or reversal of the lung disease. Decisions regarding discontinuation of drug therapy must consider the relative severity of the lung disease and the IBD, because drug discontinuation may result in a flare of IBD. Table 79-2 summarizes toxicity patterns associated with common IBD drugs. An excellent resource for drug-associated pulmonary disease can be found online at Pneumotox.com.

Table 79-2 Biopsy-Proven Lung Changes Related to Drugs Used in Inflammatory Bowel Disease (Other than Infection)

Drugs	Lung Conditions
Mesalazine Sulfasalazine Balsalazide Olsalazine (5-aminosalicylic acid derivatives)	DAD, EP, OP, HP, chronic interstitial pneumonia
Azathioprine	DAD
6-Mercaptopurine	ND
Methotrexate	DAD, OP, HP, chronic interstitial pneumonia, pulmonary edema, granulomatous inflammation
Infliximab Adalimumab	DAD, EP, OP, chronic interstitial pneumonia
Certolizumab Natalizumab	ND
Cyclosporine	Pulmonary edema
Mycophenolate	Chronic interstitial pneumonia

DAD, diffuse alveolar damage (adult respiratory distress syndrome); *EP*, eosinophilic pneumonia; *HP*, hypersensitivity pneumonitis; *ND*, none documented; *OP*, organizing pneumonia.

TREATMENT

There are no prospective randomized trials for the treatment of respiratory complications in IBD patients. Before any immunosuppressive therapy is begun, the possibility of superimposed bacterial infection must be considered. Inhaled and systemic corticosteroids are the mainstay of therapy because these agents rapidly improve symptoms and pulmonary function, as well as imaging, biopsy, and lavage findings. The effectiveness of infliximab and the newer antibodies adalimumab, certolizumab, and natalizumab in thoracic disease remains to be studied. Their use as first-line agents is currently not recommended. *Infliximab* has been found to improve extraintestinal manifestations other than lung disease. Its use may be justified if corticosteroids are insufficient. Mycophenolate mofetil, despite some anecdotal responses, has no proven efficacy and a high incidence of patient intolerance, preventing its use in IBD patients.

EMERGENCIES

The following three thoracic conditions require immediate attention and emergency treatment:

- *Acute upper airway* (glottal and epiglottal) *inflammation* can rapidly lead to airway occlusion and asphyxiation. Treatment should be initiated immediately and should include high-dose corticosteroids and, if needed, securing the airway by intubation, tracheostomy, or laser ablation. Initial corticosteroid administration in this situation should occur intravenously with conversion to oral therapy later. The clinical and visual diagnosis can be confirmed by biopsy of the airway mucosa. A patient with Crohn disease reportedly improved on initiation of infliximab therapy.
- *Diffuse infiltrative lung disease* may result in acute respiratory failure requiring intubation and mechanical ventilation. The two most common differential diagnoses must be ruled out: pulmonary infection, by bronchoscopy with lavage and culture, and drug toxicity, by withdrawal of IBD drug therapy. No evidence shows that surgical lung biopsy improves outcome in these patients; however, it may help guide corticosteroid therapy and rule out infection or other underlying diseases more confidently.

- *Acute pericarditis* with a large pericardial effusion threatening compression or tamponade may require pericardiocentesis or surgical drainage.

AIRWAY INFLAMMATION

Airway inflammation should be treated early and aggressively by administration of inhaled corticosteroids. A high initial dose (e.g., 1500-3000 µg/day of beclomethasone, fluticasone, budesonide, or equivalent in divided doses) is recommended until relief of symptoms or "best" lung function is attained. Effect of treatment can be followed with PFTs, which should be compared to the initial best values attained. Collaboration of the patient is essential, and patients should be instructed to return promptly when symptoms recur or fail to improve. Incomplete response or intermittent flares may be increasingly difficult to control with time.

Inhaled corticosteroids are most effective in large airways inflammation and are less effective in patients with bronchiolitis or bronchiectasis. In some, oral corticosteroids may be necessary and beneficial in addition to inhaled corticosteroids. A common dosing protocol is the administration of prednisone at an initial dose of 0.5 to 1 mg/kg/day, in single or divided dosing, for 4 weeks and then tapered over another 4 to 8 weeks, although the optimal duration of therapy has not been well established. Patients with marked bronchiectasis or abundant suppuration with copious sputum production may respond less well to inhaled corticosteroids and require systemic therapy from the beginning. In most severe cases, 1500 to 2000 µg of nebulized budenoside may increase topical delivery of the medication. Some have even proposed bronchial lavage fluids containing 40 to 80 mg of methylprednisolone, dissolved in 50 to 125 mL of isotonic saline two or three times per week, in addition to inhaled and oral corticosteroids.

Monitoring symptoms, pulmonary function, radiographic changes, and potential adverse effects of corticosteroids (e.g., infection) is essential. No evidence supports antibiotic treatment with macrolides or fluoroquinolones (e.g., erythromycin, azithromycin, ciprofloxacin), although these drugs have shown some efficacy in patients with diffuse panbronchiolitis. In patients receiving high-dose corticosteroids or in those with bronchiectasis, these agents may be useful, and an empirical trial may be justified.

AIR SPACE AND INTERSTITIAL LUNG DISEASE

In patients with infiltrative lung disease and imaging or pathologic findings of OP or EP who are exposed to sulfasalazine, mesalazine, or methotrexate, these medications should be withdrawn. Ensuing clinical improvement supports a drug etiology. Rechallenging the patient with sulfasalazine or mesalazine may induce tolerance and allow continued treatment of the IBD. Despite some reports of successful rechallenge with methotrexate, it is not advised because of its potentially life-threatening adverse effects on the lungs. After infection and drug toxicity are excluded, nonspecific interstitial lung disease, OP, and EP tend to respond well to oral or intravenous corticosteroid therapy. Classification of infiltrative lung disease by histologic diagnosis is preferred over empirical treatment.

SEROSAL DISEASE

Patients with pleuritis or pericarditis usually respond well to nonsteroidal antiinflammatory drugs and corticosteroids. NSAIDs should be tried first as monotherapy, with subsequent addition of corticosteroids if necessary. High-dose corticosteroid treatment with 1 mg/kg/day of prednisone or equivalent is recommended and can be tapered after 2 to 4 weeks when symptoms have resolved and C-reactive protein has normalized. A slow taper is important because it seems to assist in preventing relapse.

CONTROVERSIES AND PITFALLS

A growing number of case reports and screening studies suggest that both subjective respiratory symptoms and objectively diagnosable disorders of the respiratory system are common in IBD patients. Although pulmonary disease in these patients has been recognized for more than four decades, it is likely underdiagnosed and its true frequency underestimated. Diseases of the large airways, such as bronchiectasis, are relatively common and well-accepted extraintestinal manifestations of IBD. However, the spectrum of respiratory system abnormalities is varied, and it remains a challenge to determine whether findings described in case reports and small studies represent true pulmonary manifestations of IBD versus sequelae of IBD therapies or concomitant but unrelated disease. In particular, diffuse parenchymal lung disease, which is uncommon, has been reported to encompass a range of histopathologic patterns and is confounded by known pulmonary toxicities of common IBD therapies. Current management of these conditions is extrapolated from experience in patients without IBD, which may or may not be applicable in all cases. Prospective studies with appropriately chosen control groups are needed to help define the natural history of pulmonary manifestations and guide the development of longitudinal screening and management recommendations.

CONCLUSION

Latent or mild involvement of the respiratory tract appears to occur in up to 50% of patients with inflammatory bowel disease. The distinctive pathologic changes are much less common but potentially serious and associated with significant long-term morbidity. These changes may precede a diagnosis of IBD, occur during a quiescent phase of the disease, or develop years after colectomy. It is important to diagnose and treat airway disease early in its course to prevent disabling symptoms and the development of bronchiectasis. Infection and drug toxicity are the main differential diagnoses to exclude in infiltrative lung disease.

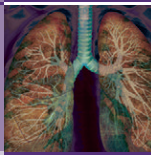
SPECIAL CLINICAL CONDITIONS



Chapter 80
Air Pollution

Seppo T. Rinne • Joel D. Kaufman

Air pollution is a heterogeneous mix of suspended solids, liquids, and gases. Even in the absence of human activity, aerosols are emitted by volcanic activity, windstorms, wildfires, and ocean waves. Traditionally, however, the term *air pollution* refers to the human impact of biomass and fossil fuel combustion, primarily from industry and vehicular traffic. The focus of this chapter is on the air pollutants with the most evidence of ongoing and widespread threat to public health, including both outdoor and indoor pollutants. Specific topics related to air pollution, including environmental tobacco smoke, plant antigens, and windblown agricultural dusts, are primarily addressed in other chapters.

HISTORY

Air pollution has posed a threat to human health since the advent of fire, 500,000 years ago. Evidence of soot in prehistoric caves indicates that early humans were exposed to high levels of indoor air pollution. Outdoor pollution began to rise as populations grew and clustered in cities. During the Industrial Revolution, there was a dramatic increase in coal use by factories and households. The resulting smog caused significant morbidity and mortality, particularly when combined with stagnant atmospheric conditions. During the Great London Smog of 1952, heavy pollution for 5 days caused at least 4000 excess deaths (Figure 80-1). This episode highlighted the relationship between air pollution and human health and, together with other episodes, led to clean-air policies in Europe and in the United States. Over the next several decades, with improvements in the regulatory framework, air quality in the developed world steadily improved. Even as energy consumption and greenhouse gas emissions have increased, pollutants that are toxic to humans have been better controlled. Nevertheless, 186 million Americans, or 60% of the population, still live in counties with levels of air pollution higher than U.S. Environmental Protection Agency (EPA) standards (Figure 80-2). Air pollution also continues to be a growing problem in cities and households of the developing world.

COMPOSITION OF AIR POLLUTION

Many different substances are considered “air pollutants,” which typically exist in combination in the environment; these include *particulate matter* (PM), carbon monoxide (CO), ozone (O_3), nitrogen oxides (NOx), sulfur oxides (SOx), and *volatile organic compounds* (VOCs). The composition varies by season and regions, and the chemistry, state, and size of a pollutant influence the resulting health effects (Figure 80-3). Although CO has specific toxicity affecting oxygen transport, many pollutants appear to cause disease by triggering injury through inflammation and oxidative stress. Physiologic effects can be confirmed by experimental studies, but health impacts of air pollution on populations can be difficult to attribute to a single pollutant because they often share sources and vary together. A multipollutant approach to understanding health effects is becoming more common. Nevertheless, this section discusses some of the physiologic effects of individual pollutants before a description of the health outcomes seen with exposure to air pollution.

Particulate Matter

Among air pollutants, PM is most consistently associated with increased mortality effects at ambient exposure concentrations regularly encountered today. Although PM can be formed by a wide variety of natural and man-made processes, one of the largest sources of PM pollution is through combustion of biomass and fossil fuels. PM is composed of organic and inorganic compounds that vary greatly in size (Figure 80-4). *Fine* PM (<2.5 μm) has the most well-recognized health effects, and the *ultrafine* PM fraction (<0.1 μm) may be especially important. Larger PM is filtered and trapped in the proximal respiratory tract, but fine particles can penetrate deep into the lung, where they are efficiently deposited, cause local effects, and may be systemically absorbed.

The composition of PM also influences its health effects. The mechanism of PM toxicity in the lung is still being elucidated but is likely multifactorial and can include impaired ciliary function, damage to epithelial cells, inflammation, and oxidative stress. Neutrophils and macrophages phagocytize the poorly soluble particles and initiate inflammatory cascades. PM also causes oxidative stress by generating reactive oxygen species (ROS) on the surface of particles that may then cause cellular effects. Inflammation and oxidative stress apparently provoke cardiovascular disease through atherosclerosis, thrombogenesis, vasoconstriction, and reduced heart rate variability (Figure 80-5).

Epidemiologic studies have associated changes in PM with respiratory symptoms, respiratory tract infections, impaired pulmonary function, asthma exacerbations, chronic obstructive pulmonary disease (COPD), cardiovascular events, cerebrovascular accident (CVA, stroke), lung cancer, and all-cause mortality.

Ozone

The stratospheric ozone layer is a normal part in the Earth’s atmosphere that absorbs high-frequency ultraviolet (UV) rays and protects us from their damaging effects. In contrast, ground-level ozone is an air pollutant, which has harmful respiratory and cardiovascular effects. Ground-level O_3 is largely the result

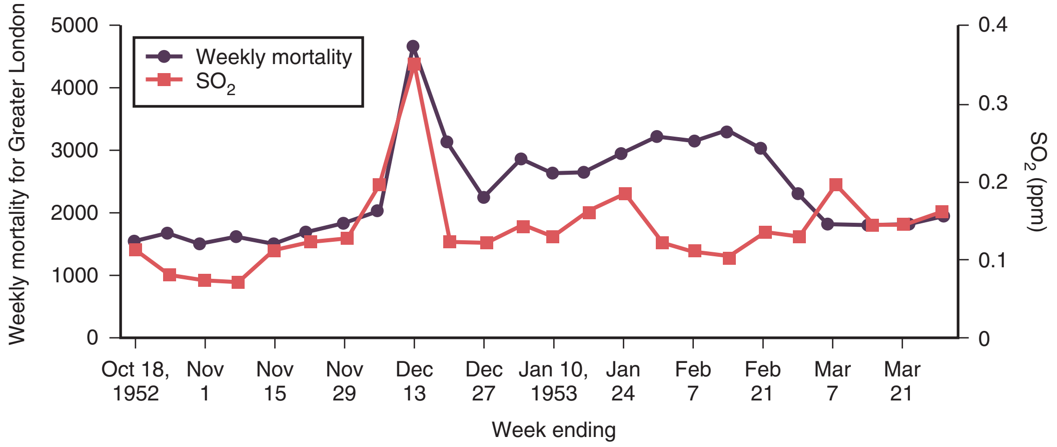


Figure 80-1 Weekly mortality in greater London, October 1952 to March 1953; So_2, oxygen saturation. *(Modified from Bell ML, Davis DL: Reassessment of the lethal London fog of 1952: novel indicators of acute and chronic consequences of acute exposure to air pollution,* Environ Health Perspect *109(suppl 3):389–394, 2001.)*

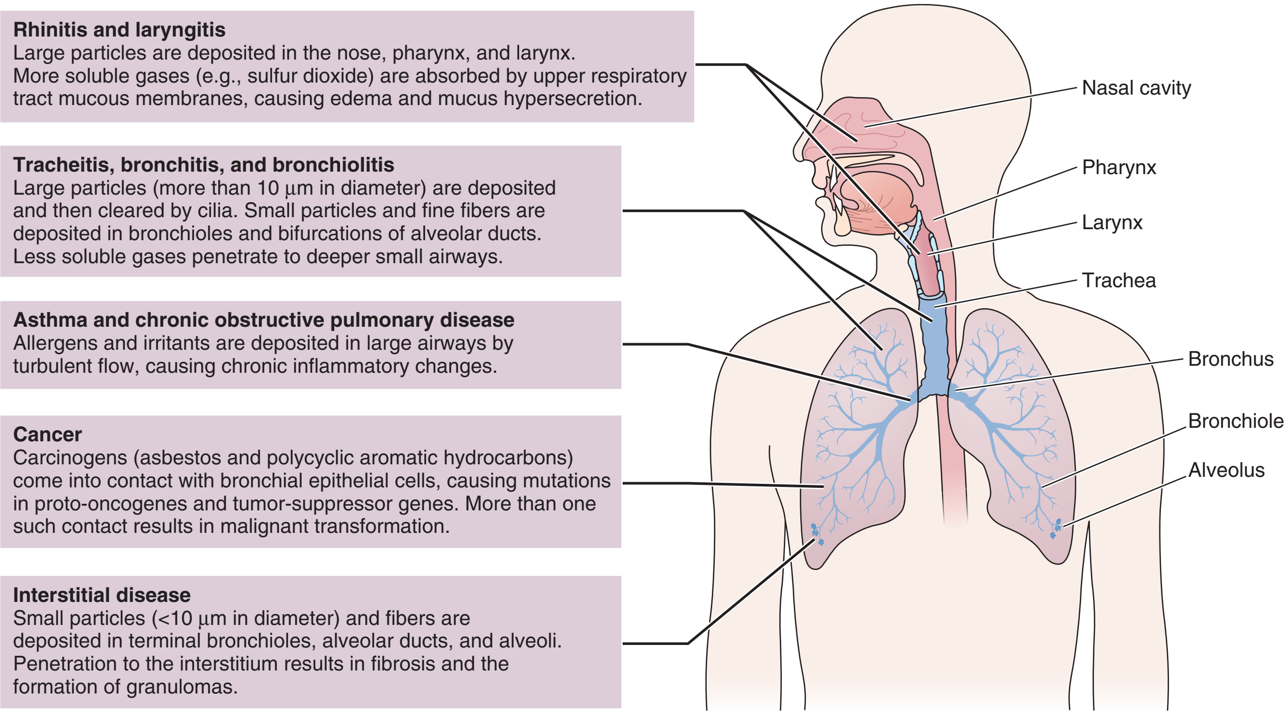
of UV photolysis of NOx and VOCs (products of vehicular and industrial combustion). Inhaled O_3 reacts with biomolecules to form free radicals, which trigger proinflammatory and prooxidative mediators. Increased neutrophils, eosinophils, and inflammatory cytokines have all been noted in bronchoalveolar lavage (BAL) fluid in response to O_3 exposure. Exposure to even very low levels of O_3 leads to airway inflammation and bronchoconstriction. Clinically, exposure to O_3 causes exacerbation of asthma and COPD, impaired pulmonary function, and increased respiratory symptoms, and it has been associated with increased mortality. The effects of O_3 are further potentiated by exposure to PM.

Sulfur Dioxide

Combustion of sulfur-containing fuels, including coal and petroleum, produces sulfur dioxide (SO_2), a highly water-soluble gas that is readily absorbed in the mucosa of the eyes and upper respiratory tract. SO_2 is a strong irritant that leads to local inflammation. SO_2 can also bind to organic PM and affect the distal airways. SO_2 increases vascular distention, mucosal edema, smooth muscle contraction, and intraairway secretions. Lung function in healthy individuals is relatively resistant to the effects of considerable doses of SO_2 (5 ppm), but even lower doses (e.g., <1 ppm) elicit acute and substantial bronchoconstriction in some asthmatic patients. Although SO_2 causes multiple respiratory symptoms, it does not seem to be independently responsible for air pollution–related mortality.

Nitrogen Dioxide

Nitrogen dioxide (NO_2) is formed during the combustion of fossil fuels, predominantly at power plants and in vehicles. Being relatively insoluble, NO_2 is not significantly absorbed by proximal mucosa. Instead, NO_2 travels to the more distal airways, where it reacts with water in the respiratory tree to create nitric acid. HNO_3 causes both local and systemic inflammation. Acutely, this can lead to bronchospasm. NO_2 is



Rhinitis and laryngitis
Large particles are deposited in the nose, pharynx, and larynx. More soluble gases (e.g., sulfur dioxide) are absorbed by upper respiratory tract mucous membranes, causing edema and mucus hypersecretion.

Tracheitis, bronchitis, and bronchiolitis
Large particles (more than 10 µm in diameter) are deposited and then cleared by cilia. Small particles and fine fibers are deposited in bronchioles and bifurcations of alveolar ducts. Less soluble gases penetrate to deeper small airways.

Asthma and chronic obstructive pulmonary disease
Allergens and irritants are deposited in large airways by turbulent flow, causing chronic inflammatory changes.

Cancer
Carcinogens (asbestos and polycyclic aromatic hydrocarbons) come into contact with bronchial epithelial cells, causing mutations in proto-oncogenes and tumor-suppressor genes. More than one such contact results in malignant transformation.

Interstitial disease
Small particles (<10 µm in diameter) and fibers are deposited in terminal bronchioles, alveolar ducts, and alveoli. Penetration to the interstitium results in fibrosis and the formation of granulomas.

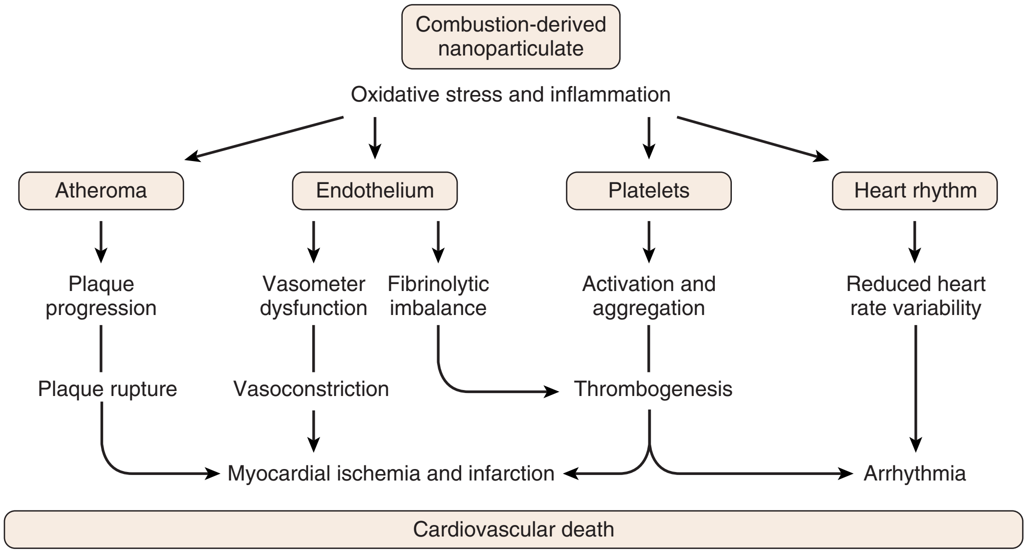

Figure 80-5 Mechanism of cardiovascular disease from exposure to air pollution. *(From Mills NL, Donaldson K, PW Hadoke, et al: Adverse cardiovascular effects of air pollution,* Nat Clin Pract Cardiovasc Med *6:36–44, 2009.)*

generally less potent than other pollutants and is likely to have its most harmful effects by acting in synergy with these other compounds. Although high levels of indoor NO_2 can increase susceptibility to viral infection, this has not been observed with outdoor levels of NO_2 pollution. In epidemiologic research, NO_2 concentrations are often considered a surrogate for exposure to traffic-related air pollution; thus the relationship of NO_2 with disease in these studies is probably caused by other pollutants that share exposure profiles.

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) include a number of organic molecules that are found in biomass and fossil fuels or are formed in their combustion. Use of these fuels aerosolizes PAHs along with other VOCs. Although there are many different types of PAH, small and lipophilic PAHs are the most readily absorbed in the respiratory tract. The effects of each PAH species depends on its underlying composition and structure. Many PAHs are irritants to respiratory mucosa. Others, such as benzo[a]pyrene, one of the carcinogens first described, and the dioxins, are mutagenic and carcinogenic, with special concern regarding cancer of the mouth, nasopharynx, larynx, and lung.

OUTDOOR AIR POLLUTION

Outdoor air pollution is influenced by the source of emissions and the surrounding environment. In recent decades, motor vehicles have become a predominant source of pollution, particularly in urban areas. Coal and fossil fuel combustion also continue to be a major source of emissions from industry and power plants. Together, vehicles and power generation make up 90% of outdoor air pollution in the United States. Other sources include biomass combustion from wood fires. During winter months, wood burning is a principal source of pollution in some parts of the United States.

Topography, climate, and local legislation further impact the air quality. In Los Angeles the nearby mountains trap pollutants, largely from local mobile vehicular sources, and intense UV rays act to create high O_3 levels. In Pittsburgh, a major city with some of the highest PM levels in the United States, most pollution is now largely derived from regional sources, carried by southeasterly winds bringing emissions from more distant power plants and factories. Outside the developed world, there are fewer environmental controls, resulting in higher levels of pollution, especially in areas of rapid industrialization and urbanization. China has many of the most polluted cities in the world, a factor of its heavy coal use and limited environmental protection.

HEALTH EFFECTS OF OUTDOOR AIR POLLUTION

Outdoor air pollution has many diverse health effects, ranging from mild respiratory irritation to hospitalization and death. The World Health Organization estimates that an excess 800,000 deaths occur annually because of exposure to outdoor air pollution. Daily fluctuation in levels of air pollution causes an acute increase in mortality, mostly from cardiovascular causes. Chronic air pollution exposure also contributes to morbidity and mortality through a variety of cardiopulmonary illnesses. Some of the first evidence for mortality of chronic exposure to PM was demonstrated by the Six Cities Study, in which citizens of six U.S. cities (representing a range of air pollution severity) were studied as a prospective cohort. Cities with higher levels of fine PM had an increased risk of all-cause mortality (risk ratio, 1.26 for most polluted vs. least polluted city; Figure 80-6). Many other cohort studies confirm this relationship, with improved determination of exposures and health outcomes.

Acute Respiratory Illnesses

Exposure to air pollution produces acute changes in lung function in healthy adults. These changes usually go unnoticed by patients who are not predisposed to bronchospasm. Among patients with asthma and COPD, however, exposure to pollution can lead to serious effects. Asthmatic patients experience increased cough, wheezing, breathlessness, and medication needs on days with high air pollution. Hospitalizations for asthma, COPD, and pneumonia all increase as air pollution rises. There are also more respiratory symptoms and upper respiratory infections in the general population. Even small changes in PM concentration can lead to these effects

(**Figure 80-7**). For every 10 µg/m^3 rise in PM, there is approximately 1% increase in all respiratory diseases. Although this effect size seems small, it has a notable impact when applied to large populations.

Chronic Respiratory Illnesses

Just as acute exposure to air pollution can cause transient changes in pulmonary function, chronic exposure to pollution is associated with structural and functional lung changes. Studies show that children living in more polluted areas have lower forced expiratory volume in 1 second (FEV$_1$). In patients with cystic fibrosis, exacerbations are more common in communities with higher PM$_{2.5}$ concentrations (PM <2.5 µm in diameter). One study observed that exposure to air pollution in pregnant women led to subsequent impaired lung development in children. There is also evidence that exposure to pollution may contribute to the pathogenesis and incidence of asthma among children. Children living close to motor vehicle traffic have been found to have higher prevalence of asthma and smaller FEV$_1$ after controlling for potential confounders. European and U.S. cohorts also show that children exposed to higher amounts of air pollution have a higher incidence of asthma.

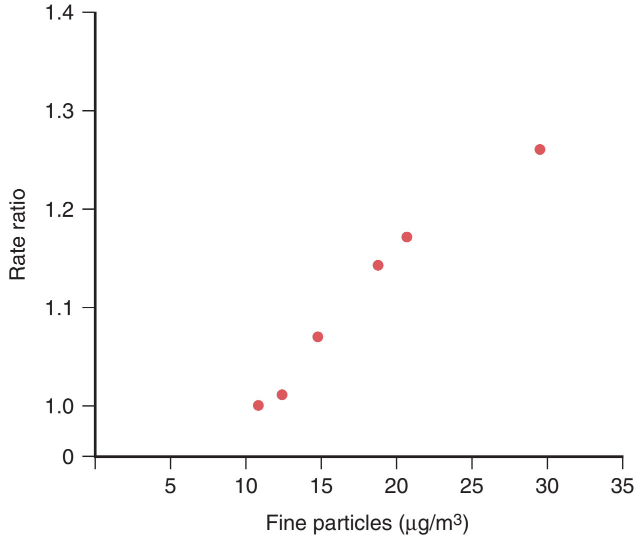

Figure 80-6 Association of fine particulate concentration and mortality from Harvard Six Cities Study. *(Modified from Dockery DW et al:* N Engl J Med *329:1753–1759, 1993.)*

The association between outdoor air pollution and the development of COPD is less clear, with studies showing inconsistent and inconclusive results. The greatest risk factor for COPD remains tobacco smoke. However, air pollution causes recurrent respiratory symptoms and infections, both of which may contribute to COPD. Similarly, data are limited on the association of outdoor air pollution and lung cancer. Lung cancer is a rare disease with a long latency period, although a few studies found a modest increase in lung cancer with exposure to outdoor air pollution.

Nonrespiratory Illnesses

Some of the most important and well-studied diseases associated with air pollution are cardiovascular illnesses, including ischemic heart disease, arrhythmias, congestive heart failure, and sudden cardiac death. A metaanalysis on air pollution and hospital admissions found that for every 10 µg/m^3 increase in PM, there was 0.8% increase in heart failure admissions and 0.7% increase in ischemic heart disease admissions. Driving or otherwise being in traffic has been associated with an acute increase in risk of myocardial infarction (odds ratio, 2.92), although pollution is only one potential culprit. Air pollution has further been associated with ventricular arrhythmias, implantable defibrillator shocks, and atrial fibrillation. The majority of excess deaths associated with air pollution are from cardiovascular causes. There is less conclusive data on the association of air pollution with other nonrespiratory diseases, including stroke, peripheral vascular disease, deep venous thrombosis, and adverse perinatal outcomes.

GENETICS AND AIR POLLUTION

There has been substantial investigation of respiratory gene-environment interactions with special attention to the ambient air pollution. This research may ultimately inform identification of not only especially susceptible populations but also

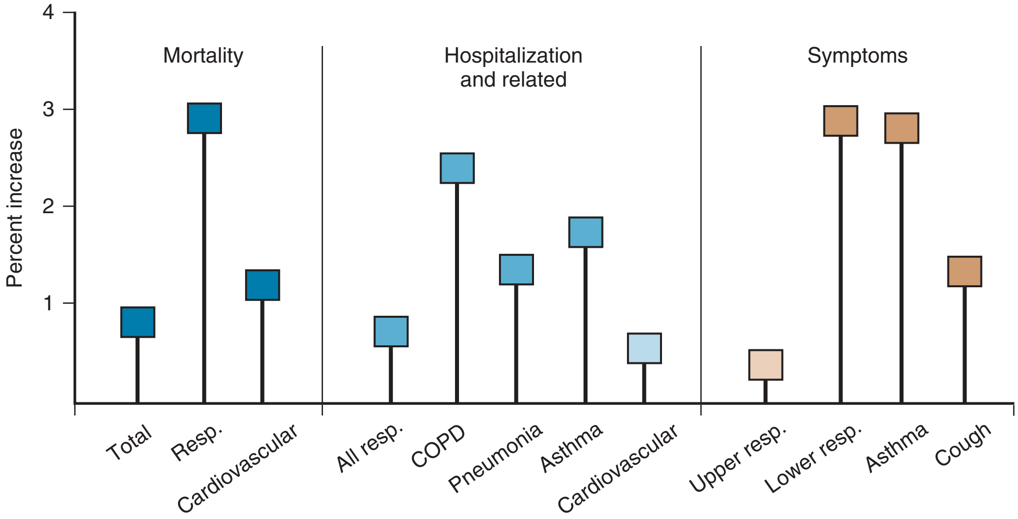

Figure 80-7 Meta-analysis results demonstrating the increase in mortality, morbidity, and symptoms associated with acute, 10 µg/m^3 increase in PM$_{10}$. *COPD*, chronic obstructive pulmonary disease; *resp.*, respiratory. *(Modified from Donaldson K, Mills N, MacNee W, et al: Role of inflammation in cardiopulmonary health effects of PM,* Toxicol Appl Pharmacol *207(2 suppl):483–488, 2005.)*

molecular mechanisms involved in the environmental effect. Genes that regulate inflammation and oxidative stress play a significant role in modulating these individual differences. Several studies have identified polymorphisms in oxidative stress genes (*NQO1*, *GSTM1*, and *GSTP1*) and inflammatory genes (TNF) that are associated with respiratory symptoms, decreased pulmonary function, and risk of asthma. For example, *NQO1* (NADPH:quinone oxidoreductase 1) is an ROS scavenger. Mutations in this gene have been associated with decreased FEV_1 in healthy individuals exposed to ozone. Polymorphisms of *NQO1* are also correlated with higher rates of asthma among children in Mexico City. Identifying genetic susceptibilities to air pollution not only helps characterize individuals who are at the greatest risk, but also helps target interventions. A clinical trial of children with a mutation in the antioxidant gene *GSTM1* found a protective effect of antioxidants, including vitamins C and E, on pulmonary function. Further studies are needed to characterize these genetic susceptibilities further and focus interventions.

AIR QUALITY INDEX

Governmental agencies worldwide measure and report on the air quality in major cities and suburban areas. The U.S. EPA produces an Air Quality Index (AQI) for more than 100 U.S. cities and regions. The AQI is reported on a scale from 0 to 500, with higher values being more hazardous (Table 80-1). An AQI score more than 100 indicates unhealthy air quality, especially when compounded by high-risk weather conditions, such as hot and sunny days. Many newspapers, weather reporters, and radio stations report this score. On days with high AQI scores, it is recommended that people stay indoors as much as possible. Susceptible individuals should also limit physical activity, which increases ventilation and ultimately leads to five times the amount of PM deposition in lungs.

Table 80-1 **Definitions of Air Quality Index (AQI) Levels by U.S. Environmental Protection Agency**

AQI Levels of Health Concern	Numeric Value	Description
Good	0-50	Air quality is considered satisfactory, and air pollution poses little or no risk.
Moderate	51-100	Air quality is acceptable; for some pollutants, however, there may be a moderate health concern for a small number of people unusually sensitive to air pollution.
Unhealthy for sensitive groups	101-150	Members of sensitive groups may experience health effects; the general public is not likely to be affected.
Unhealthy	151-200	Everyone may begin to experience health effects; members of sensitive groups may experience more serious health effects.
Very unhealthy	201-300	Health alert; everyone may experience more serious health effects.
Hazardous	301-500	Health warnings of emergency conditions. The entire population is more likely to be affected.

Data from www.airnow.gov. Accessed March 2011.

INDOOR AIR POLLUTION

The vast majority of adverse health effects related to air pollution likely occur in developing countries, where there are higher levels of both outdoor and indoor air pollution. More than half of the world's population depends on solid fuel as the primary source of domestic energy for cooking and heat. Most of this is in rural regions of the developing world where cooking is done over open fires in poorly ventilated homes (Figure 80-8). This creates intense exposure to *indoor air pollution* (IAP) with devastating health consequences.

Among households that rely on solid fuels for energy, approximately 95% use *biomass* fuels (wood, charcoal, crop residues, dung) in open indoor fires. Household coal use is less common and is primarily used in parts of China and South Africa. Overall, solid fuels are less efficient and have greater emissions than costlier fuels such as gas and electricity. In fact, although developed countries use several times more energy per household, the fuels used are cleaner with less exposure to pollutants. These differences in domestic energy are referred to as the "energy ladder" (Figure 80-9).

Combustion of solid fuels can emit many of the same chemical pollutants as outdoor pollution, including PM, CO, NO_2, SO_2, and PAHs, although the concentrations of these substances tend to be much higher. For example, concentrations of PM in households that rely on solid fuels often reach levels more than 100 times greater than outdoor concentrations. Women and children are disproportionately exposed to this pollution. On average, women in the developing world spend 3 to 7 hours per day near the fire, preparing food. They frequently do so with large children by their side and small children on their backs. As the population with the greatest exposure to IAP, women and children also suffer the most damaging health effects.

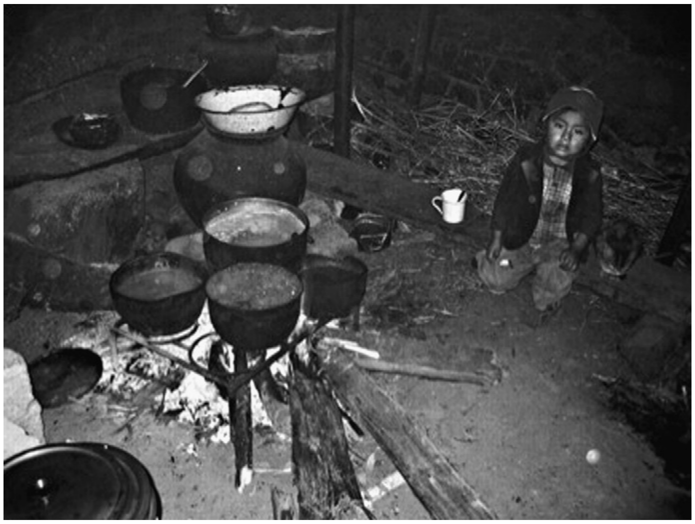

Figure 80-8 Ecuadorian child sitting next to indoor cooking fire. *(From Rinne ST, Rodas EJ, Rinne ML, et al: Use of biomass fuel is associated with infant mortality and child health in trend analysis,* Am J Trop Med Hyg *76:585–591, 2007.)*

HEALTH EFFECTS OF INDOOR AIR POLLUTION

The World Health Organization estimates that exposure to solid fuel smoke causes 1.6 million deaths annually, primarily in the developing world (Figure 80-10). This includes deaths caused by pneumonia, COPD, and lung cancer (Table 80-2). Increasing evidence also is revealing the role of IAP in other infectious and noninfectious diseases. Most diseases associated with outdoor pollution are also linked to IAP exposure. Overall, IAP is responsible for 38.5 million disability-adjusted life years (DALYs), making it the 8th leading cause of DALYs and 11th cause of death worldwide.

Acute Respiratory Illnesses

Worldwide, acute lower respiratory tract infections are the most important cause of mortality in children younger than 5 years. Exposure to IAP more than doubles the risk of developing acute lower respiratory infections. Annually, this leads to 910,000 of the 2 million deaths caused by pneumonia. Several studies also show an association between indoor air pollution and upper respiratory infections, including otitis media and mastoiditis. In addition to infectious diseases, exposure to indoor smoke leads to increased airway reactivity, which can exacerbate asthma and COPD.

Chronic Respiratory Illnesses

Chronic exposure to indoor smoke causes a broad range of chronic disorders referred to as *domestic acquired particulate lung disease* (DAPLD) or "hut lung." DAPLD includes noninfectious, nonmalignant diseases such as COPD and pulmonary fibrosis. Women who cook with solid fuels are three times more likely to develop COPD than women who cook with cleaner fuels. Globally, IAP causes 22% of COPD cases. Although most people exposed to chronic indoor smoke develop obstructive pulmonary function, some also have *restrictive* patterns. Bronchoscopy typically reveals anthracotic plaques. Computed tomography (CT) may demonstrate a variety of patterns, including reticulation, peribronchial thickening, nodules, and ground-glass opacities (Figure 80-11). Although studies are still few and inconsistent, some reports find a higher incidence of asthma among children exposed to indoor smoke.

Strong evidence links indoor coal smoke to lung cancer, again with most research from China, where coal use is common. Coal smoke has high concentrations of carcinogenic PAHs. Chronic exposure to coal smoke doubles the risk of lung cancer. Few studies have examined the relationship between lung cancer and other solid fuels; but the concern is that exposure to these pollutants also increases risk of malignancy.

Nonrespiratory Illnesses

As discussed previously, exposure to particulate matter from outdoor air pollution has consistently been associated with cardiovascular disease and mortality. Research on similar effects of indoor smoke is minimal, although the same relationships should hold true. If these risks were consistent among households cooking with solid fuels, IAP would represent a major risk factor for morbidity and mortality worldwide.

Unvented cooking with solid fuels has been associated with *poor pregnancy outcomes*, including low birth weight and increased perinatal mortality. This is likely caused by a complex interaction of pollutants in solid-fuel smoke, including PM and CO. PM predisposes to maternal illness affecting fetal growth, whereas CO avidly binds hemoglobin and decreases oxygen delivery to the placenta. On average, babies born to households that cook with biomass fuels weigh 63 g less than those born in households that use cleaner fuels.

Cataracts are common in the developing world and frequently lead to blindness. Large epidemiologic studies in India have shown a 30% increase in cataracts among people living in households dependent on solid fuels after adjusting for confounding factors. The mechanism for this effect remains a matter of speculation.

CONTROVERSIES AND PITFALLS

Environmental influences on respiratory health cannot be interpreted in isolation. Not only are these environmental factors inherently interacting with the genetic predisposition of the individual, but various environmental processes are closely linked. Changes in air pollution are associated with changes in climate, and both are currently driven primarily by fossil fuel combustion. As global warming progresses, it is likely to affect air pollution patterns, although the impact is still uncertain. Global climate change is driven by greenhouse gases, such as carbon dioxide and methane, which are not generally considered to have direct health effects at ambient concentrations. Nevertheless, warmer days are associated with worse air quality, and most scientists believe that climate change will significantly increase the number of summer days that exceed air quality standards. This change in climate will likely increase ground-level ozone as warmer temperatures promote O_3 formation. In contrast, particulate matter levels could conceivably decrease, if global warming leads to increased precipitation or a concerted effort at reducing fossil fuel use.

CONCLUSION

Additional research is needed to define the effects of outdoor air pollution in a multipollutant context. Most published research examines the health effects of individual pollutants, while the interaction between multiple pollutants and the role of particular sources of pollution is likely just as important. Ongoing research should also focus on identifying safe levels of air pollution and effective ways of decreasing exposure to pollution. In the developed world, research into clean energy may provide valuable answers to improving human health as well as the environment. In the developing world, solutions relating to improving indoor air quality and decreasing solid-fuel dependence would also have a widespread and dramatic impact.

  thymic, 849-850, 849f
Carcinoma, thymic, 849, 849f
Cardia, achalasia of, 100f
Cardiac function, chest wall deformity and, 757-758, 758t
Cardiac output
  increased, for hypoxemia, 44
  measurement of, using pulmonary artery flotation catheter, 448-449, 449b, 449t, 450f
  thermodilution measurements of, 449, 449b, 450f
Cardiac sarcoidosis, 614
Cardiac tamponade, echocardiographic features of, 199, 200f

Cardiogenic pulmonary edema, noninvasive mechanical ventilation for, 432-433
Cardiomyopathy
  peripartum, 906-907
  restrictive, secondary to chronic respiratory disease, echocardiographic features of, 200-201
Cardiopulmonary decompensation, in scoliosis, 759
Cardiopulmonary exercise testing (CPET), 143-153
  for chronic dyspnea, 259, 259t
  clinical indications for, 143
  clinical protocols for, 147-150
  constant-work rate exercise in laboratory, 149
  exercise intensity in, energy requirements and, 144-145
  incremental, in laboratory, 143, 147-148
  interpretation strategies for, 151, 152f
  patient preparation for, 151
  in preoperative evaluation for lung resection, 873, 874f
  procedures for, 151
  simple, outside laboratory, 149-150, 149f-150f, 150t
Cardiovascular system
  corticosteroid toxicities affecting, 217t
  disorders of
    chest pain in, 270
    in COPD, 546
  examination of, in COPD, 548
  imaging of, MRI in, 73
Cartilaginous bronchi, 2-3, 3f
Caspofungin
  for bacterial pneumonia, 363
  for invasive aspergillosis, 343t
Castleman disease
  mediastinal lymphadenopathy in, 855
  multicentric, in HIV patient, 377
Catamenial pneumothorax, 835
Cataracts, from indoor air pollution, 944
Cathelicidins, in lung host defense, 284
Catheterization
  central venous, in critical illness, 446-447, 447b
  heart, right-sided, in pulmonary arterial hypertension, 717-718
  pulmonary artery, in critical illness, 447-448, 447f, 450f
Catheters, pleural, indwelling, placement of, for pleural effusions, 824, 824f
Cavitating tumors, CT appearance and clinical characteristics of, 671t
Cell biology, 12-17
  intracellular signals in, 12-14
  maintenance of extracellular matrix in, 14-15, 15f
  repair in, 15-17, 16f
Cell-mediated immunity, defects in, pathogens associated with, 330, 332t
Cell senescence, in COPD, 542
Cellular nonspecific interstitial pneumonia, 603-604
Central chemoreceptors, in ventilation, 51f, 52
Central fatigue, respiratory muscle, 57
Central nervous system (CNS)
  acute disorders affecting, 768-769, 770f
  chronic disorders affecting, 769-770
  corticosteroid toxicities affecting, 217t
  depression of, respiratory acidosis from, 47-48
  in dyspnea, 251, 251f
  sarcoidosis involving, 615
Central nervous system tuberculosis, 387-388
Central neurogenic hyperventilation, in stroke, 768, 770f
Central respiratory drive, in obesity hypoventilation syndrome, 750
Central respiratory stimulants, for COPD exacerbations, 565-566
Central venous catheterization, in critical illness, 446-447, 447b
Centrilobular emphysema
  cystic air spaces in, 118, 119f
  pathology of, 533-534
Centrilobular nodules, in extrinsic allergic alveolitis, 678, 678f, 678t
Cerebellar degeneration, in lung cancer, manifestations and treatment of, 807t
Cerebrovascular accident, respiratory presentations of, 768, 770f
Cervical lymph node biopsy, 877t, 878
Cervical mediastinoscopy, diagnostic application of, 877t, 878-879, 879f
CF. *See* Cystic fibrosis (CF).
Chemical asphyxiants, 683t, 686-687
Chemical irritants, 683-686, 683t
Chemical pleurodesis, chest tube with, for malignant pleural effusions, 868
Chemokines, in lung host defense, 286-287, 287t
Chemoreceptors
  central, in ventilation, 51f, 52
  peripheral, in ventilation, 51f, 52
Chemotherapy
  adjuvant
    for Stage I non–small cell lung cancer, 802
    for Stage II non–small cell lung cancer, 803
  for malignant pleural mesothelioma, 843-844
  restaging lung cancer patients after, 178
  for small cell lung cancer, 806
  for Stage III non–small cell lung cancer, 803-805, 804t
  for Stage IV non–small cell lung cancer, 805
Chemotherapy lung, parenchymal patterns in, 235
Chest drain. *See* Chest tube.
Chest examination, in COPD, 547-548
Chest pain, 267-274
  causes of, 268b
  clinical presentation of, 269, 270f

Stenotrophomonas maltophilia, in cystic fibrosis lung disease, 575
Stenting, tracheobronchial, 167-168, 168f
Stereotactic body radiotherapy, for Stage I non–small cell lung cancer, 802
Sternocleidomastoid muscles, 54
Straight back syndrome, 78
Strength training, for ventilatory muscles, in COPD, 558-559
Streptococcus species, in community-acquired pneumonia, 298
Streptomycin, for TB, 392t
Stress
  endoplasmic reticulum, as intracellular signal, 13-14, 13f
  oxidative, as intracellular signal, 12-13
  prenatal, childhood asthma and, 498
Stress ulcer, prophylaxis for, in intubated patients, 324
Stretch receptors, 51f, 52
Stridor, 252-253
Stroke, respiratory presentations of, 768, 770f
Strongyloides stercoralis infection, in HIV patient, treatment of, 367
Strongyloidiasis, 320
  eosinophilia in, 622
  in HIV patient, 358, 358f

Subaortic fossa, mediastinal anatomy at, 109f
Subcutaneous emphysema, from chest tube leakage, 866-867
Subcutaneous pneumothorax, 834-835, 835f
Subdiaphragmatic placement, of chest tube, 866
Sulfur dioxide
  in air pollution, 938
  as irritant, 683t, 685
Superior mediastinal masses, CT evaluation of, 111-112, 112f
Superior sulcus tumors, treatment of, 805
Superior vena cava
  dilatation of, imaging of, 99, 101f
  obstruction of (SVCO), stenting for, 76
Superior vena cava stenting, 76
Superior vena cava syndrome, in lung cancer, manifestations and treatment of, 807-808
Supraclavicular lymph node biopsy, 877t, 878
Surface tension, 23-24, 24f
  of airway fluid, obstructive sleep apnea and, 739
  interstitial pressure and, 33
Surfactant. *See* Pulmonary surfactant.
Surgery
  for bronchiectasis, 586
  venous thromboembolism and, 693-694
Sweat testing, in cystic fibrosis diagnosis, 571, 572f
Sympathetic ganglia neoplasms, 858-859, 858f
Synchronized intermittent mandatory ventilation, 415-416, 416f
Syndrome of inappropriate secretion of antidiuretic hormone (SIADH), in lung cancer, 789-790
  manifestations and treatment of, 807, 807t
Systemic diseases, rare, pulmonary manifestations of, 674
Systemic inflammation, COPD exacerbations and, 562
Systemic lupus erythematosus (SLE), 653
  clinical features of, 660, 660f
  diffuse alveolar hemorrhage and, 729
  pleural effusions secondary to, 829
Systemic sclerosis (SSc), 653
  aspiration pneumonia in, 659
  clinical features of, 658-659
  interstitial pneumonia in, 653, 658-659, 658f
  pulmonary hypertension in, 659

T

Tacrolimus, in lung transplantation, 901t
Takayasu arteritis, 727-728
TB. *See* Tuberculosis (TB).
Telangiectasia, hemorrhagic, hereditary, genetic factors underlying, 8t-9t
Temporal arteritis, 727
Tendinitis, chest pain in, 270-271
Tension pneumothorax, 834
Teratoma(s)
  anterior mediastinal masses from, 112-113, 113f, 852, 852f
  benign, 813, 814f
Terbutaline
  chemical structure of, 205f
  formulations, doses and duration of action of, 207t
Tetanus, respiratory presentations of, 769
Tetracyclines, for sarcoidosis, 618
Tetralogy of Fallot, 100f
Tetraplegic patients, chest wall motion in, 53-54
Thalidomide, for sarcoidosis, 617t, 618
Theophylline
  for asthma, 510
  as bronchodilator, 209-210
    formulations, doses and duration of action of, 207t
  for COPD, 555t, 556
    relative potency and dosages of, 218t
  for COPD exacerbations, 565
  metabolism of, in COPD, 210t
  with salmeterol, for COPD, 555t, 556
Thermal ablation, for Stage I non–small cell lung cancer, 802-803
Thermodilution, transpulmonary, with arterial waveform analysis, 451, 451b, 451f
Thermodilution curves, 450f
Thermoplasty, bronchial, for asthma, 514
Thoracentesis
  in pleural effusion diagnosis, 820
  for pleural effusions, 824
Thoracic aorta
  abnormalities of, imaging of, 97-98, 98f-100f
  aneurysm of, 97-98, 99f
Thoracic cage
  diseases of, clinical features of, 764-765, 764t
  radiographic anatomy of, 78, 79f
Thoracic pump, during sleep, in scoliosis, 758
Thoracoscopy
  for pleural biopsy, 823
  video-assisted, diagnostic application of, 877t, 879-881, 880f
Thoracostomy, tube, 862. *See also* Chest tube insertion.
Thoracotomy
  open, diagnostic application of, 881
  for pleural biopsy, 823
Thorax
  disorders of, 774
  imaging of, in acute dyspnea, 254-255
  structure of, 19, 20f
  surgery of
    chest tube insertion and management for, 862-868. *See also* Chest tube insertion.
    diagnostic, 876-881. *See also* Diagnostic thoracic surgery.
    for lung transplantation, 882-903. *See also* Lung transplantation.
    postoperative complications of, 869-873, 870t
      risk factors for, 869-871, 870t
    postoperative measures for, 873-874
    preoperative measures for, 873
    pulmonary evaluation before, 869-875
      ASA classification for surgical candidates in, 871t
      for lung resection surgery, 872-873
      for surgery in general, 871, 871b
    surgical management for, 873
Throat swab, in pneumonia pathogen identification, 292
Thrombin inhibitors, direct, for pulmonary embolism, 703
Thrombocytopenia, heparin-induced, venous thromboembolism and, 694-695
Thromboembolic disease
  chronic, treatment of, 705, 705f
  pulmonary, in pregnancy, 907-909, 908f, 908t
Thromboembolic pulmonary hypertension, chronic, 713
Thromboendarterectomy, pulmonary, for pulmonary artery hypertension, 720
Thrombolytics, for pulmonary embolism, 703-704
Thrombophilia, inherited, 690-693, 691t. *See also* Inherited thrombophilia.
Thrombophlebitis, superficial, migratory, in lung cancer, 790
Thymectomy, 849
Thymolipoma, 853, 853f
Thymoma, 811, 846-849
  clinical findings in, 847t
  imaging of, 847-848, 848f
  treatment of, 848-849
Thymus
  carcinoid of, 849-850, 849f
  carcinoma of, 849, 849f
  CT imaging of, 110
  cysts of, 853, 854f
  hyperplasia of, 854
  neoplasia of, anterior mediastinal masses from, 112, 112f
Thyroid
  CT imaging of, 110
  superior mediastinal masses from, 111, 112f
Tidal volume (VT), 21, 21f
  in acute lung injury–acute respiratory distress syndrome management, 27
  in ARDS management, 461-462
  ventilator-induced lung injury and, 459-460, 459f
Time-cycled ventilation, 407, 407f
Tiotropium (Spiriva)
  chemical structure of, 205f
  for COPD, 555, 555t
  with formoterol, for COPD, 555t, 556
  formulations, doses and duration of action of, 207t
  with salmeterol
    with COPD, 556
    and fluticasone for COPD, 555t, 556
Tissue Doppler imaging (TDI), in peak systolic velocity of lateral tricuspid annulus displacement measurement, 194-196, 195f
Tissue sampling. *See* Biopsy(ies); Percutaneous biopsy procedures.
TLC. *See* Total lung capacity (TLC).
TMP-SMX. *See* Trimethoprim-sulfamethoxazole (TMP-SMX).
Tobacco. *See* Smoking/smoke exposure.
Tobramycin, for *P. aeruginosa* infection in cystic fibrosis, 575-576
Tocolytic pulmonary edema, 906
Toll-like receptor-2 (TLR-2), 284t, 285
Toll-like receptor-3 (TLR-3), 284t, 285
Toll-like receptor-4 (TLR-4), 284t, 285
Toll-like receptor-5 (TLR-5), 284t, 285
Toll-like receptor-9 (TLR-9), 284t, 285
Toll-like receptors (TLRs), 284-285, 284t, 285f
Tomography
  computed, 65-68, 66f. *See also* Computed tomography (CT).
  optical coherence, 164-165, 164f
